Garnet	Talc
Germanium	Tantalum
Hafnium	Tin
Iron	Titanium
Kyanite	Tungsten
Manganese	Yttrium

Recovery of iron:

Solid waste
Heavy media (ferrosilicon)

The newer, high-intensity, high-gradient magnetic separators open up other areas of magnetic treatment that have been pursued in varying degrees to date. Some of these potential applications are indicated in the following material:
Mineral beneficiation in addition to those systems listed above:

Antimony	Magnesium
Arsenic	Mercury
Asbestos	Mica
Beryllium	Platinum-group metals
Bismuth	Radium
Cadmium	Scandium
Coal	Silicon
Cobalt	Silver
Copper	Sulfur
Feldspar	Tellurium
Gallium	Thallium
Gold	Thorium
Graphite	Uranium
Indium	Vanadium
Lead	Zinc
Lithium	Zirconium

Water treatment (magnetic filtration):
- Diamagnetic suspended solids (by magnetic seeding and flocculation)
- Dissolved solids (by magnetic seeding and flocculation)
- Paramagnetic suspended solids
- Oils

Waste treatment for recovery of ferromagnetic materials:
- Coal and oil ash
- Ore tailings
- Smelter and furnace dust

Figure 14. High-intensity disk-type magnetic separator
a) Disk-shaped induced magnet; b) Feed belt Enlargement: a) Coil; b) Pole; c) Ring; d) Belt

Removal of paramagnetic particulate impurities:
- Chemicals
- Fluids
- Minerals
- Pharmaceuticals

Chemical processing:
- Recovery of paramagnetic fine precipitates: deposition and recovery of substances on ferromagnetic particles.

The selection of a particular magnetic separator will be influenced by several factors such as

1) size of feed material,
2) tonnage or capacity to be handled,
3) relative magnetic responsiveness (i.e., susceptibility) of the material to be separated magnetically,
4) condition of feed material (wet, dry, or liquid slurry),
5) purity required in the ferro- or paramagnetic concentrate or the diamagnetic product,
6) temperature of the feed material and point of application,
7) material handling system involved,
8) operating cost parameters, and
9) level of magnetic strength required.

1. Introduction

Electrostatic separation is the common term for all processing technologies utilizing electric forces acting on charged or polarized particles in a static electric field. The behavior of the particles depends on their electrical and geometrical properties. Therefore, a separation of different species is possible if the parameters of the electric field and the ambient conditions are set up in the right way.

Some of the basic principles of electrostatic separation have been well known since ancient times. THALES OF MILETUS (600 B.C.) observed that an amber rod attracts dust particles after being rubbed with a cloth. Electrostatic effects have first been utilized around 1880 for agricultural purposes in the separation of chaff from grain. Further applications became possible after the necessary electrical equipment for high-voltage charging of particles had been available. Nowadays numerous industrial installations, processing millions of tons of salts, iron ores, titanium ores, beach sands, and other minerals, are on stream, demonstrating the potential of this technology.

2. General Principles

An electrostatic separation process consists of the two steps: charging and separation. Charging is the key factor in all electrostatic separations due to its paramount importance for the process. Charging can be effected by either induction, corona discharging, triboelectrification, or polarization. The first three charging mechanisms involve charge transfer to or from a particle and every separation process on this basis is called *electrophoresis*. The fourth mechanism is not accompanied by a charge transfer, the corresponding separation process is called *dielectrophoresis*. In dielectrophoresis the particles remain neutral in contrast to electrophoresis where ionic particles are the species to be separated. *Electrophoresis* and *dielectrophoresis* can take place in fluids, liquids, and gases. In the narrower sense the term *electrophoresis*, however, is used for separation of organic molecules in liquids, especially for the separation of proteins and nucleotides (→ Electrophoresis). To avoid a misunderstanding this term will not be used further in this article. Charging of a particle will occur only on its surface, not within the entire particle. Therefore the factors rele-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b02_20

vant to charging are surface specific. The most important physical property is the surface conductivity of a given particle. On the one hand a high surface conductivity will facilitate charging of a particle. On the other hand discharging of a previously charged particle will occur much easier when its conductivity increases. Whether the conductivity of a given material can be utilized for an electrostatic separation or not has to be considered from case to case. In addition the surface work function of a given material is important for charging, especially for triboelectric charging. The polarity and maximum potential difference between particles of two materials to be separated are to be determined by the difference in their work functions. Another property of relevance is the dielectric constant of the particles, especially for dielectrophoresis. The higher the dielectric constant of a particle, the easier a separation will be. A high difference in the characteristics of the materials to be separated thus favors their separation.

The conductivity, the work function, and the dielectric constant of a given solid surface are not unique properties characteristic for a given material: They highly depend on ambient conditions such as temperature, moisture, and the presence of chemicals, that influence the structure and chemical composition of the particle surface. Attached to a particle surface is at least one layer of adsorbed molecules, water in most cases. Adsorbed water will lead to a rapid discharge of previously charged particles. Therefore in most cases heating in advance of an electrostatic separation step is necessary to remove water. At 100 to 150 °C only physically adsorbed water will be removed. But heating to higher temperatures usually is not economically feasible and in addition will impede sufficient charging. The surface properties often can be affected by treatment with chemicals, such as carboxylic or hydrofluoric acids. This will generate new electronic states on surface and increases or decreases the ability of a given material to become charged. If a carefully selected chemical is employed and the charging is carried out under appropriate conditions with respect to humidity and temperature, a selective charging can be achieved even in difficult cases (see Section 3.1.1).

Success of an electrostatic separation strongly depends on the particle size of the materials involved. To achieve an efficient separation by electrostatics, the upper limit for the particle size is 2 – 8 mm, depending upon the particle's density. Larger particles will be less affected by the electric field due to their higher weight and thus the higher gravitational force acting on them. When material with too broad a particle size distribution is fed, classification will interfere with the electrostatic effect, leading to a poor separation. Particles below 40 µm will adhere to the larger particles or to the electrodes and therefore cannot be processed by standard separators. For this kind of particles special separator types have to be employed (see Sections 2.2 and 3.4). An appropriate screening of the materials has thus to be carried out before feeding them to an electrostatic separator.

The separation itself can be effected either in a uniform or a nonuniform electric field as shown in Figure 1. Each of the field types finds special technical applications. Uniform electric fields are only employed as d.c. fields whereas nonuniform fields are also used as a.c. fields, the latter being the case in dielectrophoresis (Fig 1 B, see also Section 2.3).

Figure 1. Principles of electrophoresis and dielectrophoresis
A) Electrophoretic force on charged particles; B) Dielectrophoretic force on neutral particles

There are numerous publications describing the general principles of electrostatics and its application for separation purposes in detail. Examples are given in [1,2,3,4,5,6,7,8].

2.1. Charging by Induction or Corona Discharge

Since these two charging mechanisms reveal great similarities with respect to the physical fundamentals, the apparatus, and the applications, they will be described in the same section.

2.1.1. Charging by Induction

A schematic image of an apparatus usually employed in electrostatic separation by inductive charging is shown in Figure 2. The mixture to be separated is fed onto a grounded rotational drum and passes through the electric field generated by a high voltage tubular electrode. In most cases the electrode is negatively charged, but a positive charging is in principle possible as well. The conductive particles get charged by induction for a short period of time, depending on their surface conductivity. The induced charge has the inverse polarity to that of the high voltage electrode. Therefore an attractive force towards the electrode will be imposed on the conductive particles. These particles are deflected from the surface of the rotor in the direction of the electrode and can subsequently be collected in an appropriately positioned bin. The nonconductive particles are not significantly charged during their residence on the rotor or their charge will be too small to affect a motion towards the high voltage electrode. Thus they remain on the rotor until they will fall into a collecting bin under the influence of gravitational force or will be scraped down by a brush.

Figure 2. Rotational drum separator – inductive charging

Devices for electrostatic separation via induction – so-called electrostatic drum separators – can only be applied for separation of conductive particles from nonconductive ones. Although separation of particles having large differences in surface conductivities would be possible in principle, in practice this has never been done with success on a large scale. Electrostatic drum separators are especially employed for final cleaning of industrial products such as rutile, zircon, or food, e.g., tea leaves (see Section 3.4).

2.1.2. Charging by Corona Discharge

This kind of electrostatic separation works similar to the induction based process and is described schematically in Figure 3. In contrast to inductive charging all particles – conductive and nonconductive ones – are charged due to the high field strength produced by the ionizing corona electrode generating an ion stream. The corona electrode usually consists of a thin wire or a needle type electrode. The charge of the conductive particles and semiconductors rapidly migrates to the grounded rotor whereas the nonconductive ones remain charged for a longer time due to their higher surface resistivity. They are attracted to the rotor and follow its movement. Finally they are scraped down by a brush and collected in a bin. The neutralized conductive particles fall down into their corresponding bin.

Figure 3. Rotational drum separator – corona charging

Electrostatic separation via corona charging – so-called corona separation – can be employed

for the separation of particles with different conductivities. In contrast to electrostatic drum separators corona separators provide a wider range of applicability due to the stronger field employed.

2.1.3. Separators

Drum separators are the most widely used separation devices. Examples for the use of this technology are the beneficiation of mineral sands [9, 10] and iron ores [11, 12], the production of iron superconcentrates [13, 14] and the processing of waste electric wire [8, 15, 16] (see also Chap. 3).

Extensive work has been done to understand the theoretical fundamentals leading to a better modeling of the electrostatic separation process. For designing an industrial installation, however, thorough experimental work on both laboratory and pilot plant scale has to be carried out. The key factors affecting the performance of a rotational drum separator, that have to be investigated for every electrostatic process plant, are

1) Conductivity of the particles
2) Dielectric constant of the particles
3) Density of the particles
4) Particle size
5) Particle shape
6) Rotary speed of the drum
7) Structure of the electric field.

Many of these topics have been discussed above. The dependence on the particle shape is shown in the shape separation process designed by Knoll et al. [17]. The specifically constructed separator and the controlled electric field led to an improvement of the recovery of coarse vermiculite from siliceous gangue. The flatter vermiculite is more efficiently attracted to the rotor than the gangue. The latter behaves like a conductor and can be separated from the vermiculite.

For electrostatic drum separators usually metallic tube electrodes are used. For enhancement of separation efficiency the applied voltage has to be increased. In order to prevent an electrical breakdown when the electrode voltage is increased, nonconductive coatings have been introduced. Vacuum discharge tubes made of glass are also widely used now [18].

The needle or wire electrodes of corona separators are often additionally equipped with tubular high voltage electrodes. This will enhance separation of the nonconductive or less conductive particles when they are deflected towards the electrode. For the arrangement of the corona electrode and the high voltage electrode in general two cases are possible as shown in Figure 4 [19]. The "pinning" geometry has become more prevalent especially in the mineral sands industry. A further improvement of separation can be carried out by combining the corona electrode with more than one high voltage electrode. As shown in Figure 5, depicting the separation of copper from PVC in a laboratory study, the copper content of the conductor fraction can be increased up to 99.6 % by the action of three additional high voltage electrodes. In industrial applications one electrode with elliptical cross section replaces the three tube electrodes, resulting in the same efficiency [8].

Figure 4. Combination of corona electrodes and static high voltage electrodes
A) "Pinning" geometry; B) "Lifting" geometry

Some new electrostatic separators have also been developed to improve the performance of drum separators. Some principle examples are shown in Figures 6, 7, 8. The combination of a high voltage electrode or corona electrode and a grounded counter electrode or moving device is a common feature of all these special machines. The structure of the specific separator depends on the characteristics of the materials, conductivity, particle size, amount of feeding, etc. Besides multiple drum machines the most important devices are belt-type and plate-type separators. For example, the separation of carrot and celery seed lots for selection of those with the best germination has been carried out on a

Figure 5. Influence of the electric field on electrostatic separation of metals and insulators [14]

Figure 6. Moving belt separator – inductive charging

Figure 7. Moving belt separator – corona charging

Figure 8. Plate-type separator – inductive charging

belt-type separator [20]. The *plate-type separator* has the advantage of absence of moving parts thus decreasing maintenance expense and stand-stills. It was developed primary for separation of low amounts of conductive minerals from zircon concentrates [3].

2.2. Triboelectric Charging

2.2.1. Mechanism

The well known phenomenon that two different materials will acquire different charges when rubbed against each other is the physical basis for this method of charging. Charging of particles can occur either on contact with particles of the other component in the mixture or on contact with the material of the charging device as demonstrated in Figure 9. When a mixture of the charged material is allowed to free-fall in an electric field formed by two oppositely charged electrodes, the materials will be separated as shown in Figure 10. The polarity of the charge of a specific material received upon rubbing depends on the particular material it is to be separated from, more precisely on the difference in the electron work functions of the materials

Figure 9. Triboelectric charging of particles
A) Particle – particle contact; B) Particle – material contact

Figure 10. Separation in the electrostatic field

to be separated. All materials can be arranged in a series according to the polarity of charge acquired by that rubbing procedure, the *triboelectric series*. This matter has been the object of numerous investigations, because there is no unique series in which a specific material occupies a given position like, e.g., every chemical element in the periodic table. Depending upon the experimental conditions several triboelectric series exist [21]. The fundamentals of triboelectrification have been the object of many investigations and great advances have been made in the last years [7, 22, 23, 24, 25, 26, 27]. Nevertheless, a complete understanding has not yet been achieved. Therefore equipment design needs extensive laboratory tests and pilot plant studies as in the case of drum separators.

The effectivity of charging depends not only on the chemical composition of the materials to be separated but also markedly on the humidity of the ambient atmosphere, the particle size distribution, and the history of the particle surfaces. This can be understood by consideration of the fact that any solid surface is covered by a layer of adsorbed molecules, originating from the ambient atmosphere. Often a modification of fresh generated surfaces by adsorption of specific chemicals is necessary to obtain a sufficient charging upon friction.

2.2.2. Equipment

Electrostatic separation by triboelectrification can be employed for the separation of both coarse particles and fine powders. For many years industrial installations were restricted to the processing of potash ores only. Since 1995 some machines have been on stream for separation of fly ash (i.e., dust particles) in the USA. Also erection of some pilot plants for the separation of mixed plastics and purification of coal has been reported, but no industrial installation is known up to now.

In contrast to rotational drum separators, in triboelectric charging the charging and the subsequent separation are more distinct operations. Charging can be carried out, e.g., in a fluidized bed, in cyclones or tubes with helix-type internals or without any inner constructions. In potash processing (see Chap. 3) only fluidized beds are employed for charging. Plastics recovery pilot plants also use this technique in the most cases. Charging for coal purification often has been carried out with the other devices.

Also in the separation step many different devices are employed. In almost all installations, especially in the potash industry, so-called free-fall separators are utilized. In such an apparatus the charged particles fall "freely" due to gravitational forces in the electric field formed by appropriate electrodes. Plate electrodes are the most simple construction for this purpose. The field is formed by two metal plates arranged in parallel. The main problem of this kind of electrode was the dust adhering to the plates that decreased the electric field strength. Attempts to overcome this shortcoming by application of vibrational devices failed, so that further developments in separator design were necessary. A step forward was the construction of vertically or horizontally working belt separators. The moving belt consisted of rubber with a conductive coating. With this type of separator a throughput up to 20 t per hour and per meter was realizable but other shortcomings prevented the employment in process plants.

The tubular free-fall separator (Fig. 11), that was subsequently developed, fulfilled the requirements for an appropriate apparatus for potash processing. The electrodes remain dust-free on their entire height and the deflected salt between the electrodes can leave the apparatus on quite a short way. This separator was developed by the German potash industry on the basis of an American separator type with motionless tubular electrodes [28]. The electrodes developed in Germany consist of two rows of rotating steel tubes facing each other. The rows are permanently kept dust-free with brushes on the sides remote from the electric field. The tubes usually have a length of ca. 2 m. The longest separators can be more than 10 m in length. The throughput is about 30 t of salt per hour and per meter. Electrode distance is 250 mm, the field strength can reach values from 4 to 5 kV/cm. The voltage is 100 – 125 kV while the current is less than 1 mA. Consumption of current for the separation itself is therefore extremely low, only caused by brush-discharge loss and leak currents. Provided that the raw salt particles have been sufficiently liberated (→ Potassium Compounds, Chap. 5.4.), particle sizes up to 1.5 – 2 mm can be processed [29]. In some cases the extent of liberation of the minerals makes a separation of particles up to 4 mm possible. However, this requires a greater length of the separator due to the higher gravity force acting on the particles.

Figure 11. Tubular free-fall separator

Other types of separators have also been developed for special purposes. The electrodes can also be arranged in a nonparallel manner, e.g., in a plate-type separator utilized for separation of plastics on a laboratory scale [30, 31, 32]. Perforated electrodes incorporated in the fluidized bed utilized for charging have been constructed for purification of fine coal [33]. The coal particles are separated from the impurities by passing the electrode whereas the impurities are rejected. A sieve conveyor is another example of separation machines specially designed for this purpose (see Section 3.2) [34]. With the latter device purification of coal particles with diameters $< 40\,\mu m$ has been reported to be possible.

Most of the separators are only employed on a laboratory or pilot-plant scale. An exception is the new belt separator shown in Figure 12 [35]. This device is constructed for separation of finest particles after contact charging. The separator consists of two plate electrodes with a distance of up to 10 mm. A mesh belt of plastics between the electrodes is utilized as transport medium for the particles. The material is charged while it is fed into the separator by an air slide. The charged particles are deflected towards the oppositely charged electrodes and are conveyed by the mesh belt to the respective end of the separator, where a sampling will be carried out. The separator has been employed with success in fly ash processing in the United States (see Section 3.4).

Figure 12. Belt separator for dust processing

2.3. Dielectrophoresis

Dielectrophoresis is the movement of neutral particles in a nonuniform electric field (Fig. 1B). It differs from the conventional electrostatic separation (electrophoresis) in the following features:

1) Dielectrophoresis produces motion of particles suspended in a fluid medium. The direction of motion is independent of the sign of the field. Accordingly, either a.c. or d.c. fields can be used. Electrophoresis on the other hand produces a motion of the suspended particles whereby the direction of the resultant path depends on the sign of the charge and the sign of the field direction.
2) Dielectrophoresis gives rise to an effect that is proportional to the particle volume and is, therefore, more easily observed on coarse particles. Contrary to that the effect of electrophoresis is observable with particles of any size.
3) Dielectrophoresis usually requires quite divergent fields for strong effect. Electrophoresis operates in both uniform and divergent fields.
4) A relatively high field strength is required in dielectrophoresis. In media of low dielectric constant, this usually amounts to some 10^4 V/m. In media of high dielectric constant, e.g., water, lower fields may be used. In contrast, electrophoresis with previously charged particles requires relatively low fields.
5) In dieletrophoresis usually a substantial difference is required between the relative dielectric constants of the particles and the surrounding medium. Electrophoresis can be appreciable even when the free charge per weight unit of the particle is quite small.

The properties of a dielectrophoretic separation vary with the medium in which separation occurs. In a dielectric field medium having an intermediate dielectric constant with respect to the feed constituents, a separation can be performed based on differences in the dielectric constants of the feed materials. Examples of intermediate dielectric fluids include nitrobenzene, kerosene, xylene, ethanol, and propanol. When air is used as a medium, separation is largely based on differences in shape, density, and dipole moment.

Although dielectrophoretic separation has been well known since the end of the 19th century [36], applications of this method are still rare (see Section 3.4). Widespread use of di-

electrophoresis has been hampered by, e.g., the environmental and health hazard of the utilized dielectric field media, difficulties in the employment of high-frequency a.c. fields in technical applied apparatus volumes, and, for a long time, the lack of understanding the mechanistic details of this technology. A review of the state-of-the-art including history is given in [37]. Dielectrophoresis is an emerging technology that will certainly provide new solutions in the area of physical separation processes.

3. Applications

Separation processes based on *inductive* or *corona charging* are the method of choice in cases of high differences in conductivity of the materials to be separated (see also Chap. 1). This encompasses processing of conductive minerals and recovery of values from electronic scrap and metal-containing manufacturing wastes. Separation of insulators such as potash and plastics however are typical cases where *tribolectrification* is employed. The applications of electrostatic separation known so far are listed in Tables 1, 2, 3. A summary of some developments is given in [38].

3.1. Mineral Processing

3.1.1. Potash Ores

In Germany electrostatic separation by tribolectrification is employed in the processing of potash ores since 1973 on an industrial scale. At present more than 15×10^6 t/a of potash ore are processed in this way.

Investigations on this separation technology began at the Minerals and Chemical Corporation (IMCC or IMC), Chicago [83,84]. Potassium chloride and sodium chloride were successfully charged by heating up to 300 – 700 °C. However, the energy demand of this method was quite high and separation results were not satisfactory. The employment of surfactants for the pretreatment of the feed made a temperature decrease to below 100 °C possible, which made the process economically feasible [65,85,86,87,88,89,90,91,92,93,94,95,96,97,98].

In Figure 13 (see next page) the amount of sylvine (KCl), kieserite ($MgSO_4 \cdot H_2O$), and halite (rock salt, NaCl) separated at the positive electrode is shown, depending on the relative humidity of the heating air. The raw salt is conditioned with aromatic monocarboxylic acids (Fig. 13A), aliphatic monocarboxylic

Figure 13. Fraction at the positive electrode
Conditioning with aromatic monocarboxylic acids (A); With aliphatic monocarboxylic acids (B); With aliphatic monocarboxylic acids and ammonium salts of aliphatic monocarboxylic acids (C)

acids (Fig. 13B), and aliphatic monocarboxylic acids in combination with the corresponding ammonium salts (Fig. 13C).

In principle any of the three aforementioned components can be separated at the positive electrode just by changing the relative humidity of the air. A better performance, however, is achieved by appropriate combination of the relative humidity and the conditioning agent. For an improvement of charging often a second agent in addition to the main conditioning agent is employed (Fig. 14).

As shown on the left-hand side of Figure 14 (conditioning with salicylic acid), a loss of $MgSO_4 \cdot H_2O$ has to be accepted to achieve a maximum yield of KCl and NaCl. Only by addition of a second agent the optimum yield of all three components is obtained. Meanwhile numerous reagents acting as conditioning agents are known. This will allow separation even of complex mineral mixtures into their components

Figure 14. Yield of K_2O, kieserite, and rock salt at the positive electrode in dependence on relative humidity, conditioning with salicylic acid (left) and salicyclic acid plus chloroacetic or lactic acid (right)

[93,94]. According to the choice of conditioning agents and humidity of the air a selective charging of the different minerals against each other is achievable. A mixture consisting of more than two components therefore can simply be separated in several subsequent process stages, e.g., as follows:

1) Separation of sylvine in the first step [84, 86,95]. Then the residue is separated into kieserite and halite.
2) Kieserite is separated first and the potash component in the following step [97,98].
3) In the first step halite is separated [88,89,90] and the residue is separated subsequently into potash and kieserite concentrate.

All three methods are performed on an industrial scale. Method (3) is employed in the largest electrostatic potash processing units at the Werra works [61,62] of the German potash industry. A principal flow sheet of an electrostatic separation circuit is shown in Figure 15. The raw salt delivered from the mine is size-reduced by impact grinding and subsequently screened. The particle size of the feed has to be adjusted carefully. To achieve sufficient liberation of the individual components of the raw salt (i.e., halite, sylvite, kieserite) the upper limit should be $< 1.5 - 2$ mm. Grains > 2 mm cannot be processed due to insufficient liberation. Additionally, the gravitational force acting on them would require greater working lengths of the separators. Fine particles (< 0.1 mm) adhere to the larger particles and thus cannot be separated (see Chap. 2).

Figure 15. Electrostatic separation circuit

Conditioning is one of the key factors in electrostatic potash processing and consists of the following steps:

1) Application of the agent or agent combination onto the raw salt
2) Adjustment of the appropriate temperature and relative humidity of the air
3) Charging of the salt by friction in air with defined relative humidity.

The application of the agent – the so-called chemical conditioning – is carried out either in the solid, liquid, or gaseous state [92], but also on inert support materials, which possess large inner surfaces [87]. About 20 – 100 g of conditioning agent per ton of raw salt are employed. After conditioning the potash mineral is charged in a fluidized bed in air with defined humidity and the subsequent separation will be done as described in Section 2.2.2.

The flow sheet of one of the electrostatic separation plants at the Werra works [29,61] of the German potash industry is shown as an example in Figure 16. The raw salt delivered from the mine contains up to 70 % of rock salt. Therefore in the first separation step halite is separated and dumped. The other fraction contains the potash minerals sylvine and carnallite as well as kieserite. The following process steps can be carried out in considerable smaller devices. After renewed conditioning in the next step sylvine

and carnallite are obtained as a potash raw fraction at one electrode, the kieserite raw fraction is obtained at the other. Purification of each fraction leads to a potash enriched fraction and a magnesium enriched fraction. The first one contains sylvine and carnallite in a higher purity compared to the previous fraction whereas the latter one consists mainly of kieserite. The residues of these purification steps are subjected to the hot leaching process, the oldest industrial potash purification process (→ Potassium Compounds, Chap. 5.2.2.). The potash enriched fraction undergoes a wet process yielding KCl employed in potassium sulfate manufacturing. The kieserite is of fertilizer quality and can be shipped as such. Small amounts of langbeinite ($K_2SO_4 \cdot 2\,MgSO_4$) and anhydrite ($CaSO_4$) do not affect this application. Further treatment of kieserite to obtain $MgSO_4$ by dewatering, however, requires a material of higher purity. For this purpose kieserite is submitted to a subsequent electrostatic separation stage. After another conditioning separation gives the required pure kieserite and a langbeinite- and anhydrite-rich kieserite. The latter is employed in the manufacturing of potassium sulfate together with KCl.

Figure 16. Flow sheet of electrostatic separation plant for potash processing

The dust (< 0.1 mm) separated from the fluidized beds is not recycled to the process. As pilot-plant tests have shown both the yield and the quality of the products will be lower when such a recycling is carried out [99, 100]. The dust will therefore be processed in the hot leaching process of the potash plant in the same way as the dust formed in the grinding step before conditioning.

3.1.2. Other Minerals

Electrostatic treatment of other minerals on an industrial scale is exclusively performed by drum separators and similar devices. Rotational drum separators were first employed for industrial applications in the 1920s. In the late 1940s this technology was first used for the extraction of titanium-bearing minerals from beach sands. The beneficiation of iron ores was first carried out in 1964 in the Wabush mines, Labrador, Canada, after extensive investigations on the laboratory scale and in a pilot plant. After successful operations of separation plants had been reported, many other applications of processes employing rotational drum separators were developed for materials such as, e.g., plastics, metals, foods, and agricultural products (see Sections 3.3, 3.4).

Iron Ore Beneficiation. In the Wabush installation the dry gravity concentrate of iron ore processing is fed into 36 rougher each having six rotational drums of 3.05 m diameter. The ore is separated in a conductor and a nonconductor fraction. The middling is retreated in 18 cleaner units. The conductor fraction leaves the circuit to form part of the final product. The nonconductor fraction is fed to the scavenger section. The conductor fraction of the cleaner units is combined with the conductor fraction of the rougher stage. The tailings of the cleaner step are retreated with the rougher tailings in the scavenger. The middling is recirculated to the rougher. The scavenger produces an iron ore fraction which is combined with the conductor fraction of the rougher and the cleaner step. The nonconductor fraction from the scavenger is completely iron-free and forms the final reject. The voltage at the electrostatic electrodes is + 25 kV. The iron product grade is reported to be 66.3 % with 98 % iron recovery [11].

Titanium Ore Separation. Rotational drum machines have been employed in processes for separation and beneficiation of titanium-bearing minerals, such as rutile, anatas, ilmenite, leucoxene, and perovskite. One of the first commercially utilized processes is the separation of rutile minerals from beach sand, of which the Sierra Leone operation will be described in the following. For an optimum separation efficiency the material circuit is divided in a fine (< 0.2 mm) and a coarse (> 0.25 mm) circuit. The heavy fraction from the wet gravity plant is fed to rougher drum separators yielding a conductor fraction and a nonconductor one. The first one is fed to the cleaner separators, the latter to scavenger separators. For the cleaner and the scavenger step also drum separators are employed. The middling of the rougher units together with the conductor fraction of the scavengers and the nonconductor fraction of the cleaner separators is added to the feed of the roughers. The conductor fraction of the cleaner step is submitted to a magnetic separation. The nonmagnetic fraction undergoes an additional electrostatic cleaning step in plate-type separators. The nonconductor fraction of the scavengers and the tailings of the magnetic separation step form the reject. The rutile concentrate leaving the final cleaning step was reported to have a TiO_2 content of 95 % (fine circuit) or 96 %, respectively (coarse circuit) with an overall rutile recovery of 88 % [11].

Separation via Triboelectrification. Besides potash processing no industrial mineral separation plant is known where triboelectrification is used. However, the potential of electrostatic separation by contact charging has been demonstrated in numerous laboratory tests and pilot plant separations. Examples are separations of feldspar – quartz, calcite – quartz, dolomite – quartz, brown coal – quartz sand. The purification of phosphate rock has also been established.

3.2. Purification of Coal

Coal contains impurities such as ash and pyrites and therefore has to be purified before combustion in order to lower the expense for flue gas desulfurization. Dry methods for purification of coal have been a focus of considerable interest for many years. Compared to well established wet cleaning processes they have the advantage of lower cost due to the fact that a drying step is unnecessary. Numerous electrostatic separators have been developed for this purpose. Among them charging via triboelectrification is most important [38]. Methods utilizing induction or corona charging have also been applied to the separation of coal from its impurities but, for the most part, these methods had only limited success [101].

One of the main characteristics of coal purification via triboelectrification is the small particle size of the coal compared to potash ore particles. In most cases particles of $< 100\,\mu m$ have to be processed, but separators exist that are able to process coal of particle size $< 40\,\mu m$. This particle size is required to ensure adequate liberation of the pyrite impurities. For particles of this size electrostatic separation in a gravitational field cannot be achieved. Instead the coal has to be conveyed by gas flow (pneumatic conveying) while passing through the electric field. The separators and installations shown in Figure 17 are examples for this technology [38]. The common feature is that finely ground coal is injected into a gas flow. The particles are charged by contacting the inner wall of the pipe. The wall consists of a material which is located in the triboelectric series between the two components (coal vs. ash/pyrite) to be separated.

Although many successful separations on the laboratory and pilot-plant scale are reported, no industrial installation is known until now.

3.3. Recycling Processes

Electrostatic separation for recycling purposes is mainly employed in recovery of values from electronic scrap and separation of wastes from polymer manufacturing.

3.3.1. Inductive or Corona Charging

Due to increasing production of wiring boards or printed circuit boards, the amount of waste arising from the production process of the boards has also increased. Whereas the boards themselves mainly consist of epoxy resin and glass fiber, they also contain significant amounts of precious metals such as gold and silver besides copper. For example, in a process designed by NEC the electronic parts mounted on the boards are separated by heating, impacting, and shearing. The boards are then pulverized to obtain a sufficient liberation of the copper incorporated in the multi-layer resin – glass fiber construction. The mean diameters of the particles are reported to range from 100 to 300 µm. The separation process consists of two steps. First the separation of the glass fiber and resin powder is carried out in a gravimetric air separator. The subsequent separation of the heavier particles is achieved by employment of a rotational drum separator via corona charging. In this step the copper particles are separated from the nonconductive ones. The copper recovery rate was reported to be > 90 % with a copper content of > 60 % in the copper fraction. The copper rich powder is used as a copper resource while the recovered resin powder is utilized in filler applications [48,49].

The other area of employment of rotational drum separators is the recovery of values from wire and cable wastes [8,15,16,52,53,54]. Each year thousands of tons of such materials arising from off-specification production and maintenance procedures are to be processed. The metals – copper and aluminum – are usually recovered by granulation and subsequent air-gravity separation. In such process schemes electrostatic separation is a useful auxiliary technology. Rotational drum separators utilizing inductive and/or corona charging are employed. Metal recovery > 90 % and a metals fraction of 99 % metallics can be achieved. Plastics recycling from chopped wire and cable on the other hand also can be achieved, yielding fractions with 99.9 % plastics and < 0.1 % metallics.

Application of rotational drum separators to recycling purposes also led to interesting developments of special separator types and electrodes (see Fig. 5). However, the employment of these type of separators so far is restricted to process streams of a few hundred kilograms per hour at the most. Therefore in huge process streams a pretreatment by other technologies, especially air-gravity separation has to be carried out to reduce the feed stream to the drum separator.

3.3.2. Triboelectrification

In Figure 18 (see next page) the densities of the most common bulk plastics are shown. As can be derived from this figure, a heavy-media separation or separation by employment of a hydrocyclone can only be achieved in the case of separating of polyethylene (PE) and polypropylene (PP) from other plastics. The situation looks much better when utilizing the different charging behavior of plastics. The triboelectric series of plastics is shown in Figure 19. In principle all plastics in this series can be separated from each other [68, 69, 70, 102, 103, 104, 105]. When two different plastics come into contact, the one on the left side in the triboelectric series will acquire a negative charge, the one on the right side a positive one. The greater the distance of two plastics in the triboelectric series the easier a selective charging will be achieved. For example, in a mixture of poly(vinyl chloride) (PVC) and poly(ethylene terephthalate) (PET), PVC will be charged negatively, PET positively. However contacting of PET with polystyrene (PS) will result in negative charging of PET and positive charging of PS.

Thus electrostatic separation of plastics by triboelectrification will preferably be employed for separation of binary mixtures. A controlled charging of mixtures containing more than two different plastics is quite difficult. An exception to this is PVC. It will always be charged negatively against all other plastics, except poly(vinylidene fluoride) (PVDF). Therefore PVC can be separated from mixtures of numerous other plastics. The plastics that could be successfully separated are listed in Table 4.

Figure 18. Densities of common plastics

Figure 19. Triboelectric series of common plastics

However, the position of a particular plastic in the triboelectric series can shift. Responsible for this effect are different additives in otherwise chemically identical polymers. Thus one particular material can become charged positively or negatively, depending on the particular additive employed in the plastic. Additives can be dyes, plasticizer, etc. Impurities also can cause a shift of the position in the triboelectric series.

The process of electrostatic separation of plastics is carried out in a similar manner as potash processing. The plastics are first conditioned and the particles are then charged against each other in a fluidized-bed apparatus. As in the case of potash processing, surfactants are used as conditioning agents and added on a ppm level. The humidity of the warming air also has to be adjusted carefully. After charging the particles are separated in an electric field by gravitational forces. The construction of the separators, however, is somewhat different from that of potash separators. Thin tubes with 2 – 3 cm diameter are employed which are arranged in a staggered configuration [106]. This is to avoid that the particles rebound from the electrodes. The distance at the end of the electrodes from each other can be adjusted for every particular separation problem. This can result in a non-parallel arrangement at the electrodes. Another innovation are flow splitters with different length. As a result the amount of impurities in the product could be decreased down to the ppm level.

Some other charging devices and electrode configurations have been developed, but the most of them are still working on the laboratory scale [30, 31, 32]. Until now no large scale industrial separation plant exists.

3.4. Others

Fly Ash Processing. The separator described in Section 2.2.2 is successfully employed in the processing of fly ash. In power plants fly ash is separated into unburned coal and ash. The coal is recycled to the burner whereas the ash is utilized in the manufacturing of building material. A couple of these installations are on stream in power stations in the United States. Up to now these plants are the only examples for successfully running electrostatic dust separation processes on an industrial scale.

Tea Leaves. Many industrial electrostatic separation installations are employed in the tea industries of Japan, Taiwan, Sri Lanka, and India to separate stalks from tea leaves. The separators often consists of two rotational drum separators arranged in sequence. Charging is carried out via induction by a high voltage electrode. The diameter of the rolls in one installation is 150 mm, the distance from the high voltage electrode ranges from 30 to 50 mm. The voltage applied is − 20 kV. After steaming, coarse rolling, fine rolling, and drying the tea leaves with a water content of 7 – 9 % are fed to the finishing process. Here the leaves are classified into powder, sprout, and leaves by screening. The leaves containing many stalks are then fed to the first of two rotational drums from a hopper. They are separated into a stalk fraction attracted by the negative high voltage electrode and a leave fraction falling down to the next stage. Here the remaining stalks are separated, yielding a pure leaves fraction. Throughput often is about 300 kg/h [38].

Electrostatic Decaffeination. An apparatus for separation of charged substances from conductive fluids is reported to be applicable to decaffeination of coffee or tea. The device consists of two chambers connected by a porous wall. One chamber including the wall is charged negatively or grounded, the other is connected to the positive terminal of the field generating assembly. The caffeine fed into the device can be concentrated in one of the chambers whereas the fluid passes the porous wall thus resulting in a decrease of caffeine content. Several special em-

bodiments have been patented for continuous or discontinuous employment of the separator [109].

Electrofiltration is primary known as electrostatic precipitation of dust particles from gas streams (→ Dust Separation, Chap. 6.). But electric fields also can be applied in solid – liquid separation as electrostatically enhanced vacuum filtration. This technology has been developed since the 1970s [73, 74]. The unit is similar to an electrolytic cell as shown in Figure 20. Two parallel plate electrodes are placed in the slurry that is to be separated. When a potential is applied across these plates, the particles in the slurry, which normally carry a net charge, are attracted to the electrode with opposite polarity and collected. The cake is then removed as the solid phase product from the electrofiltration. The filtered liquid is drawn off from both the positive and negative electrodes by vacuum methods. This type of solid – liquid separation technology has first been installed in a Georgia kaolin plant for separation of clay.

Figure 20. Electrofiltration unit

Electrofiltration can also be utilized for removing of ultrafine particles from liquids, such as, e.g., hydraulic oil [76], deionized ultrapure water for production of silicon integrated circuits [77], or kaolin-containing fats and oils from bleaching [75].

Dielectrophoresis. Dielectrophoretic separations are rarely used on an industrial scale at present and are restricted to removing catalyst fines from petroleum products, and separation of impurities (e.g., fibers) from foods. Dielectrophoresis is now being widely employed in separations of biological materials, such as, e.g., cells of yeast and *E. coli*, erythrocytes, or leucocytes [80, 81, 82]. However, these applications are laboratory methods for scientific or diagnostic work. The separation devices are quite small. Continuously working separators have been developed recently [107].

The prospect of a possible application of dielectrophoresis is provided by the effect of *selective chaining* of particles in an electric field. This means that particles with a dielectric constant higher or smaller than the dielectric constant of the medium will arrange in a linear chain along the force lines of the field. Each chain contains only particles of one species. This has been investigated for the separation of diamonds from heavy minerals of kimberlite rock [37, 108]. The separation takes place in a channel type apparatus where the chains are moving perpendicularly to the force lines of the field. In Figure 21A the cross-section of the feeding end of the channel is shown, the discharging end can be seen in Figure 21B. The high voltage electrode (a) generates the electrostatic force along the grounded flat electrode (b). The feed enters the channel through a single pipe at the mid-point of the cross-section. At the discharging end the material with the higher dielectric constant than the medium is falling through a pipe (g). The material with the lower dielectric constant is discharged through the central pipe (f). The screen (c) prevents particles from bridging the electrodes, which can lead to dielectric breakdown of the liquid medium. The walls (e) consist of insulating material. For vibrational movement of the particles the channel is mounted on a spring (d). In separation tests on diamond – kimberlite the average diamond loss is $< 0.25 - 0.3$ %. When the feed contains 3 % diamonds, the concentrate has a grade of 55 – 60 % with a recovery rate of almost 100 %.

1. Introduction

Gravity concentration is the separation of one or more minerals, usually of different density, from others by relative movement in response to the force of gravity and other forces.

Next to handpicking, gravity concentration is the most ancient mineral-processing method, with early practices described over 2000 years ago [1]. One of the classic works on the subject is the 6th century book by AGRICOLA [2]. In the 20th century, the importance of gravity concentration declined somewhat as other processes, such as flotation or magnetic and electric separation methods, were developed (→ Flotation, → Magnetic Separation, → Electrostatic Separation). Nevertheless, it remains one of the major recovery processes in both mineral processing and, especially, coal preparation (→ Coal, Chap. 7.1.2.1.). Furthermore, the development of high-capacity equipment, along with heightened awareness of the negative environmental impact of many chemicals used in flotation and leaching, has resulted in renewed interest in gravity concentration for a wide range of products.

Today gravity concentration is used for a diverse range of minerals: from andalusite to zircon, from coal to diamond, from mineral sands to metal oxides, and from industrial minerals to gold.

2. Principles

Important factors in determining the relative movement of a particle in a fluid include relative density, mass, size, and shape of the particle.

If, in a hypothetical two-mineral separation, only one of these factors is significantly different, separation is relatively easy. In nearly every case, however, the variety of minerals present have different relative densities and a range of particle masses, sizes, and shapes. The ease or difficulty of separating one species from another depends on the relative differences between these factors and whether such differences assist or oppose separation. Some idea of the ease of separating two minerals can be obtained from the *concentration criterion* (CC), which is defined as follows:

$$\mathrm{CC} = \frac{d_\mathrm{h} - d_\mathrm{f}}{d_\mathrm{l} - d_\mathrm{f}}$$

where d_h is the relative density of the heavy mineral; d_l the relative density of the light mineral; and d_f the density of the suspending fluid.

In general, if $\mathrm{CC} > 2.5$, then separation is relatively easy; however, if $\mathrm{CC} < 1.25$ separation is not likely to be effective. For developmental test work, the concentration criterion is not sufficiently accurate, and tests involving heavy-liquid separation should be carried out (→ Dense-Medium Separation, Chap. 5.).

Gravity concentration is effected by the relative movement of minerals of different density in response to gravity and one or more other forces, which often include the resistance to motion offered by a viscous fluid. One characteristic of all separation devices is that, for the particles to

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b02_21

move relative to one another, at some stage of the process the particles must be kept slightly apart, or *dilated*, by the superimposed force.

No single mechanism can satisfactorily explain the behavior of any particular device; a combination of two or more mechanisms comes closer to describing the operation (but rarely does so completely). Conversely, however, various mechanisms have been proposed that are common to apparently diverse items of equipment and gravity concentration processes, and these are a useful means of classifying the various devices (see Fig. 1) [3].

Figure 1. Mechanisms in gravity concentration
A) Density; B) Stratification; C) Flowing film; D) Shaking
○ = light; ● = heavy

Density (Fig. 1 A). The viscous fluid used has a density, or apparent density, between that of the minerals to be separated. Thus, one mineral(s) has a net positive buoyancy and floats, whereas the other(s) has a net negative buoyancy and sinks. This classification includes dense-medium separation (→ Dense-Medium Separation), one of the most important gravity concentration processes, and magnetohydrostatic separation.

Stratification (Fig. 1 B). An intermittent fluidization caused by the pulsation of the fluid in a vertical plane stratifies the various mineral constituents. This classification applies to a wide range of jigs.

Flowing Film (Fig. 1 C). The constituents are separated by their relative movement through a stream of slurry, which flows down a plane by the action of gravity. Flowing-film concentration is the oldest process used in gravity concentration and remains of major importance, with such units as the sluice, pinched sluice, Reichert cone, and, through inclusion of lateral movement caused by the addition of centrifugal force, the spiral.

Shaking (Fig. 1 D). The mineral components are stratified by superimposing a horizontal shear force on the flowing film. This force can be oscillating, as in a shaking table, or orbital, as in the Bartles – Mozley separator or crossbelt concentrator.

The theoretical aspects of these and other mechanisms involved in gravity separation are discussed in [4].

3. Choice of Equipment

A wide range of gravity concentration equipment is available. Factors that determine choice of the correct unit include the size range of the particles to be separated, the duty required, the desired throughput and efficiency, and–all other things being equal–the unit cost, both capital and operating, of the equipment.

Size Range. The overall particle-size range that can be separated by using gravity concentration is larger than for any other process. Particles can be separated from each other as long as there is a suitable density differential between them; however, the top size may be limited by the mechanical handling ability of the device, 500 mm is generally accepted as the largest size for separation. The practical lower cutoff limit for fine gravity concentration is ca. 6 µm.

No device is capable of treating the entire size range amenable to gravity concentration. In addition, few devices operating as a single unit can efficiently treat the complete range which they are designed to handle. Therefore, some form of feed preparation is normally required. Figure 2 indicates the optimum size range for some of the more common equipment types [4]. Jigs, Reichert cones, and sluices are essentially mass classification devices and are capable of treating a fairly wide range of sizes, but some loss of efficiency occurs at the top, bottom, and middle of the size range. Treatment of material in *series circuits* is practical with these units (Fig. 3).

Figure 3. Series circuit
a) Jig; b) Screen; c) Jig

Figure 4. Parallel circuit
a) Hydrosizer; b) Spiral; c) Shaking table; d) Cyclone; e) Crossbelt concentrator

Other types of equipment (e.g., the table or Bartles – Mozley separator, concentrating by reverse classification, or the spiral concentrating by hindered settling) operate significantly better on sized or classified feed, and treatment in *parallel circuits* is required (Fig. 4).

Generally, the two types of circuit are combined. For example, a series circuit of jigs treating unsized feed may be followed by a sizing step, sized fractions being heated on a parallel circuit of tables and film sizing units.

Capacity. The capacity range of gravity concentration equipment is enormous (from a few kilograms per hour to ca. 1000 t/h per unit). Whereas sluices and jigs are manufactured in a variety of sizes suited for a range of capacity, other items are produced in one or two sizes only, and high throughputs require multiple units. Typical capacities for gravity concentration equipment are as follows (in tons per hour):

Jig	$\leq$800
Sluice	$\leq$500
Reichert cone	60 – 70
Spiral	1 – 12
Table (ore)	0.2 – 2
Table (coal)	8 – 12
Bartles – Mozley Separator	2 – 2.5
Crossbelt Concentrator	0.3 – 0.5
Centrifugal	1 – 15

Efficiency. Most devices can efficiently separate materials containing only very heavy and very light fractions. However, most materials consist of particles with a range of densities. The more efficient a device, the more capable it is of effectively separating near-density particles [5].

Equipment efficiency classified by this measure is shown in Table 1.

Table 1. Process applicability–density of separation

Wt % of feed within $\pm$0.10 kg/L of density of separating medium	Degree of difficulty expected	Type
0 – 7	simple	sluices, jigs
7 – 10	relatively simple	cones
10 – 15	moderately difficult	tables spirals, DMS *
>15	difficult	DMS *

* Dense-medium separation

4. Stratification Devices

Jigs sort by movement of a bed of particles, which are intermittently fluidized by pulsation of the fluid in a vertical plane. The particles become arranged in layers, with density increasing from top to bottom. This particle arrangement (stratification) results from several continuously varying forces which act on the particles. Although many types of jigs are manufactured, their construction principles are similar (Fig. 5).

Figure 5. Basic construction of a jig
a) Jig bed; b) Ragging; c) Jig screen

Figure 6. Three mechanisms of jigging
A) Differential acceleration; B) Hindered settling; C) Interstitial trickling
○ = light; ● = heavy

Theories postulated to describe the action of the jig include differential acceleration, hindered settling, and interstitial trickling (Fig. 6). Differential (initial) acceleration at the start of particle movement is related to particle density, rather than particle size or mass. Hindered settling occurs once the particles have reached their terminal velocity; movement is related to mass. In the interstitial trickling phase, movement is related to particle size. An alternative theory proposes that the mechanism of concentration is the attainment of minimum potential energy in the heterogeneous mass [6]. Each of these mechanisms undoubtedly plays some part in the stratification process; however, which (if any) is the most important is open to question. Because the design of the pulsation cycle (i.e., duration of the cycle and the intensity of both upward and downward pulsation) can be varied, different manufacturers have developed units that accentuate different mechanisms.

Figure 7. Typical jigs
A) Baum and OPM; B) Denver; C) Bendelari; D) IHC
a) Air box; b) Jig bed; c) Screen; d) Diaphragm

Jigs that rely on a long pulsation phase and a short suction phase, such as the Baum, OPM (Fig. 7 A), and Batac coal-washing jigs, tend to have a high capacity at the expense of recovery of finer particles. Although less efficient than heavy-medium separation, the high capacity and low operating cost of these jigs ensure that they

remain the primary means of concentrating thermal coal as well as metallurgical coal where the amount of near-density shale is not excessive.

Units with a longer suction phase, such as the Denver, Bendelari, and IHC (Fig. 7 B – D), exhibit a higher recovery of fines with some compromise to capacity. Therefore, these units are more commonly used for mineral recovery, such as alluvial tin or hard-rock gold ores.

5. Flowing-Film Devices

When a film of water flows down an inclined surface under laminar conditions, the velocity distribution is parabolic, being zero at the bottom of the film and maximal at the top. When mineral particles of different size and relative density are introduced into this laminar film, they arrange themselves in the general downslope sequence shown in Figure 8. A variety of devices use this mechanism for separation.

Figure 8. Particle arrangement on an inclined surface
○ = light; ● = heavy

Sluice Box. A sluice box is essentially an inclined trough or launder, usually of rectangular cross section, through which a wide size range of feed is washed by a large volume of water. A series of riffles is arranged at the bottom of the sluice box so as to provide some turbulence between each riffle and allow concentration of heavies.

These units are relatively inefficient and generally used only for alluvial mining in areas where power is not readily available.

Pinched Sluice and Reichert Cone. The principle of operation of a typical *pinched sluice* is shown in Figure 9.

Pulp, at a high solids density, enters the channel in a relatively thin stream at the upper or wider end. As this stream flows down the sluice, the finer and heavier particles concentrate (a) in the lower levels of the stream and increase in depth as the width of the sluice decreases. At the end of the channel, the slower moving lower level of the stream, enriched in heavy minerals, is peeled away from the main stream by a splitter (b).

Figure 9. Pinched sluice
A) Cross section: a) Concentrating segment; b) Splitter
B) Plan view

A variety of pinched sluice designs are used, especially in Australia. Elsewhere, the more common variant is the *Reichert cone* (Fig. 10). The inverted cone concentrating surface of this device may be viewed as a number of pinched sluices placed adjacent to one another to form a circle, without any sidewalls to interfere with stratification [7]. The cone concentrator consists of a number of stages in series and in parallel; it can thus achieve multiple stages of separation in one unit. This is important because neither cone nor sluice is particularly efficient in a single stage.

Figure 10. Reichert cone
a) Feed distributor; b) Double-cone assembly; c) Adjustable insert; d) Single-cone assembly; e) Variable insert

The advantages of the Reichert cone are its high capacity, low capital cost per unit throughput, light weight, compactness, and metallurgical performance. Cones have two disadvantages: one is the need for a feed with 60 % solids because the device is sensitive to variations in pulp density; the other is that cones are unsuitable for operations with a new feed rate of less than ca. 50 t/h.

Spiral Concentrator. Spiral concentrators are used widely in mineral processing and, more recently, in coal preparation. The basic design of the spiral has remained virtually unchanged for many years (Fig. 11).

Figure 11. Spiral concentrator
a) Center column; b) Splitter; c) Wash-water channel; d) Concentrate pipe

Recently, however, spiral technology has developed rapidly, more so perhaps than that of any other gravity concentrator. Developments, mainly in Australia, the former Soviet Union, the Peoples Republic of China, and the United States, have included the introduction of a range of trough profile, pitch, and diameter; the introduction of limited offtake spirals; and the use of spirals that do not require wash water [8]. The correct choice of these parameters for a specific duty is probably the most important factor in efficient spiral flow sheet design.

Concentration in a spiral is a complex blend of a variety of forces: hindered settling classification, interstitial trickling, Bagnold shear, and stream cross-sectional rotation. Many gravity concentration devices use the first two forces, several employ the first three, but the addition of cross-sectional rotation makes the spiral unique as a self-compensating device.

6. Shaking Separators

Shaking Table. The shaking table (Fig. 12) remains one of the workhorses of the mineral-processing industry [9].

Figure 12. Shaking table
a) Feedbox; b) Wash water; c) Deck; d) Riffles; e) Shaking mechanism; f) Supports

The forces by which the shaking table separates the heavy particles from the lights are complex and, to some extent, opposing. Particles are stratified into discrete layers behind a series of riffles (Fig. 13) by superimposing, on the flowing film, a horizontal, asymmetrically reciprocating shear force acting laterally to the flow. The stratified layers are separated from each other by a lateral movement caused by the asymmetry of the shear force.

Figure 13. Stratification behind riffles

The multidecked Concenco (USA) and SKO (former states of USSR) units are ideally suited for roughing duties in larger plants and for coal preparation; the latter application is by far the most important in terms of volume. Single-deck units with mechanical head motions, such as the Holman (UK), Deister (USA), SKM (former states of USSR), Wilfley (UK and USA), and Yun Tin (Peoples Republic of China) types, are better suited for smaller plants or for cleaning duty, mainly in mineral processing. In such operations, careful feed preparation and treatment of table middlings on separate equipment are essential for optimum performance.

7. Slime Separators

The inherent difficulty of recovering very fine particles (< 50 µm) by gravity has led to the development and, in many cases, obsolescence of a more diverse range of equipment than for any other particle-size range.

The Endless Belt concentrator and Johnson barrel are used in South Africa to recover fine gold in milling circuits. Likewise, the Rocking – Shaking vanner is used in China for the treatment of tin, tungsten, and iron ores. The more widely used Bartles – Mozley separator and the Bartles Crossbelt concentrator superimpose, an orbital shear motion on a slightly inclined surface, and are capable of recoveries as fine as 6 µm. The former (Fig. 14) is a semibatch device that discharges concentrates discontinuously; the latter is a continuous device that uses a slowly moving belt to remove concentrates from the pulp stream.

Figure 14. Bartles – Mozley separator
A) Collecting step: a) Feedwater valve assembly; b) Two sandwiches; c) Product launders
B) Discharging step: d) Suspension cables; e) Tilt cylinder; f) Main frame

Spiral sluices are popular in both the former Soviet Union and the Peoples' Republic of China. Similar in principle to the spiral separator, the cross section of the helix is much flatter, enabling recoveries as fine as 15 µm to be achieved.

The GEC (General Electric Co.) Duplex concentrator uses side shear rather than orbital shear. It is a semibatch device, with the decks tilting sideways rather than lengthways as on the Bartles – Mozley separator. Centrifugal separators are growing in popularity. The Knelson concentrator consists of a riffled basket rotating on a vertical axis with a continuous supply of backpressure water in the riffles to keep the bed of ore (usually gold) mobile. The Yunnan separators used in China for iron, gold, and metal oxide recovery are smooth-walled drums rotating on a horizontal axis. Both units are semibatch devices.

8. Dry Gravity Concentration

The majority of commercially available, dry gravity concentration processes are similar in principle to their wet gravity concentration counterparts. The latter include dense media separation, jigging, pinched sluices, and tabling. Although the mechanisms of separation of the wet and dry units may not be the same, the wet units already described make a reasonable point of reference for their dry counterparts. Other dry gravity concentration devices, which do not have a direct counterpart in wet concentration, have been developed. These include the fluidized-bed separator and the zigzag.

All dry concentrating equipment, except the dry jig, uses a constant controlled upflow of fluidizing air. The dry jig, however, uses a pulsating air flow; pulsation effects stratification in a manner comparable to its counterpart in wet concentration.

Dry separators generally require closely sized feed and are less efficient than wet separators. Consequently, they are used only where water is not available, or for "cleanup" of rough concentrates already dried for other processes.

9. Flow Sheet Example

Apart from sample separations, plants rarely incorporate only one type of device. This is especially true of metal oxide plants. Figure 15 (see next page) is an example of the complex flow sheet that may be required to maximize both recovery and purity of the valuable minerals.

1. Introduction

Dense-medium separation (DMS), also known as heavy-medium separation or sink – float separation, is one of the most widely applied and most efficient gravity separation processes in both mineral processing and coal preparation. Essentially, it is a process in which particles of different relative densities are separated in a liquid or in a fairly stable suspension of predetermined density chosen such that the liquid density is higher than that of the lighter particles but lower than that of the heavier particles.

The range of operating density of separation is 1300 – 3800 kg/m^3. The medium can be any suitable fluid; however, in practice, it is invariably a suspension of fine, normally magnetic particles in water. Dense-medium separation effectively separates particles with density differentials of $<$100 kg/m^3 in the size range of 500 – 0.5 mm. The largest size is dictated by the mechanical considerations of the separating vessel; the smallest, by medium rheology.

Uses. Dense-medium separation has two main areas of application. It is used for preconcentration to obtain an economically acceptable waste product that does not warrant further treatment, such as in the processing of diamonds, sulfides, and metal oxide ores. This allows either (1) a significant reduction in the quantity of ore that requires grinding prior to other separation methods or (2) the treatment of a lower grade ore than would otherwise be economically viable. Alternatively, DMS is used to produce a salable end product, as in coal preparation and industrial mineral separation.

2. The Process

Unlike most other gravity concentration techniques, dense-medium separation is a system rather than a unit process [1]. To work effectively and economically, the system must consist of a series of interconnected phases:

1) feed preparation,
2) feed and medium presentation,
3) separation of heavies and lights,
4) product recovery and dewatering, and
5) medium recovery and recycling.

These stages are illustrated in a typical dense-medium separation circuit in Figure 1 (see next page).

In operation, the feed must be screened (a) to remove fine ore and slimes before it is fed, with reconstituted medium, to the separatory vessel (b) which separates the sinks (heavies) from the floats (lights). The vessel may be either static or dynamic; generally, the type of vessel chosen does not change the overall design concept of the circuit. Floats and sinks are withdrawn separately and are drained of most of the medium on static or vibratory screens (c) and (d). The medium is either returned directly to the system or cleaned prior to return. Next, the floats and sinks are washed on the vibratory screens to remove the remaining adhering heavy medium. The undersize products from the washing screens, consisting of medium, wash water, and fines, are too dilute and contaminated to be returned directly as medium to the separatory vessel. They are treated individually or together by magnetic separation (g) to separate the magnetic ferrosilicon or magnetite from the

nonmagnetic fines. Reclaimed, cleaned medium is thickened to the required density by a suitable densifier (h), and continuously returned to the DMS circuit. The densified medium discharge passes through a demagnetizing coil (i) to ensure a nonflocculated, uniform suspension in the separatory vessel [2].

One of the essential components of the heavy-medium separation process is the medium itself (see Chap. 4). The correct choice of medium and its effective control, in terms of both consistency and physical parameters, are essential for efficient operation of the system.

3. The Separatory Vessel

Separatory vessels can be either static or dynamic. In *static vessels*, separation (generally of particles coarser than 2 mm) is carried out at normal gravity, whereas in *dynamic vessels*, finer particles (generally limited to the range of 20 – 0.5 mm) are separated at elevated gravitational force.

Static DMS Vessels. Static vessels can be subdivided into cone, drum, trough, and combination types (Fig. 2). The feed is generally introduced at or near the top of the separatory vessel. Lights float on the surface and are removed over a weir, with or without the assistance of paddles. Removal of the sinks varies with type of vessel.

Figure 2. Types of static separatory vessels
A) Cone: a) Bath; b) Paddles; c) Screen; d) Airlift
B) Drum: a) Bath; b) Launder; c) Drum
C) Trough: a) Bath; b) Chain
D) Combination (Drewboy): a) Bath; b) Elevator
M = Medium; F = Feed; H = Heavies; L = Lights

Cone separators (Fig. 2A) contain the greatest depth of medium, which should be slightly agitated to minimize the density gradient from top to bottom of the vessel. Sinks are removed from the bottom by an internal air lift, external pump, or bucket elevator, with drained medium being recycled directly to the vessel. Cone separator circuits tend to be exceptionally stable because of the relatively large quantity of medium employed; they are especially suitable for separation of materials having similar densities.

Drum separators (Fig. 2B) consist essentially of a rotating cylindrical drum fitted with internal lifters, which elevate the heavies out of the medium bath into the sinks discharge launder. The lifters also cause some agitation of the medium, overcoming any tendency for it to settle. Drum separators are common in both coal preparation and mineral separation.

Trough separators (Fig. 2C) consist of a shallow bath or trough for the medium and a moving product removal system, which typically is a single-chain conveyor that moves the two products to opposite ends of the trough. Trough separators are used mainly in North American coal preparation plants.

Combination separating vessels (Fig. 2D), such as the Drewboy and Norwalt, are classified as shallow-bath vessels. Unlike other static vessels, the heavies removal system is not located within the medium bath itself but, like the deep cones, is a separate part of the system. These vessels, therefore, combine the advantages of the shallow bath (large heavies discharge capacity, low medium requirement, and low density gradient) with the advantages of the deep cone (division of the functions of product separation and removal). Therefore, these separators are among the most efficient available.

Dynamic DMS Vessels. Dynamic dense-medium separation was first studied by Driessen at the Dutch State Mines Laboratories with a standard hydrocyclone [3]. The higher forces involved in centrifugal separation permit much finer particles to be separated successfully. The high shear within the vessel enables finer medium, essential for stability, to be used without resulting in excessive viscosity. In addition to the cyclone, a variety of modified cyclone vessels have been developed (Fig. 3).

The smallest particle that can be effectively separated by dynamic dense-medium systems is rarely related to the separatory vessel used; rather, it is generally related to the medium recovery system. The accepted smallest size for efficient separation is 0.5 mm.

Figure 3. Types of dynamic dense-medium separating vessels
A) Cyclone; B) Swirl; C) Vorsyl; D) Dyna whirlpool; E) Triflo; F) Water-only cyclone
M = Medium; F = Feed; H = Heavies; L = Lights

The principle of operation of the dense-medium cyclone is similar to that of the conventional cyclone (→ Dust Separation , Chap. 3.) except that separation is based on particle density rather than size. Only a limited size classification effect occurs, on large or small particles

or those with a relative density close to the separating density. A typical cyclone separator is operated on an axis that is close to horizontal (Fig. 3A), whereas the Japanese swirl cyclone (Fig. 3B) operates upside down. The Vorsyl separator (Fig. 3C) is a modified cyclone with a cylindrical body; heavies leave the body via an annular throat to a secondary densifying cylinder.

In the separators shown in Figure 3A – C, medium and solids enter the separator together at high pressure (210 – 275 kPa) through the feed port; this results in high wear of feed pump and piping. In the Dyna whirlpool separator (Fig. 3D) and the Triflo separator (Fig. 3E) however, medium is pumped only into the lower tangential inlet; the feed enters by gravity at lower pressure through an axial pipe. Heavies pass through the cycloning medium and leave via the tangential sinks pipe. Lights remain on the axis of the vessel and exit through the axial discharge pipe. The Dyna Whirlpool is a single-stage unit. The Triflo separator has two stages; it can be set to produce two sink products at the same density of separation or at two different densities.

The water-only cyclone (Fig. 3F) can be regarded as an autogenous dense-medium cyclone, in that fines in the ore recirculate within the cyclone to form the medium. These cyclones are employed only in the coal preparation industry, and usually in series, because they are relatively inefficient.

4. The Medium

Although the correct choice of separatory vessel is obviously important in terms of capital and operating costs, as well as efficiency of separation, the control and efficiency of the operation are, to a large extent, dependent on the medium.

Ideally, the medium should be a true heavy liquid. However, although such liquids exist and some are used for laboratory simulations, their toxicity and cost preclude them from commercial application.

Practically, a commercial medium should

1) be available in quantity at or near the site,
2) be comparatively inexpensive at the site,
3) be noncorrosive,
4) be nontoxic,
5) form stable mixtures in water,
6) be physically and chemically stable
7) mix readily with water,
8) rinse from the product with high-pressure water sprays,
9) be capable of regeneration, and
10) be adjustable over a range of densities [4].

Dense media used for commercial separation are almost exclusively suspensions of fine insoluble particles in water. The most commonly utilized solids are *magnetite* [*1309-38-2*] ($d = 5.0 – 5.2$)and *ferrosilicon* [*8049-17-0*] ($d = 6.7 – 6.9$). Magnetite is most commonly used in coal preparation; ferrosilicon is generally chosen for preconcentration of metalliferous ores, although to reduce costs it is often mixed with magnetite. Magnetite and ferrosilicon are preferred because they can be regenerated almost completely in the medium recovery circuit by use of low-intensity magnetic separators as both recovery and densification units.

Ideally, the medium should have low yield stress, low viscosity, and high stability. Unfortunately, however, stable suspensions tend to have high yield stress and high viscosity, and vice versa. The classic work on the rheology of dense media was carried out by DeVaney and Shelton [5]. These workers showed that, for any suspension, *viscosity* (and hence apparent density) increases with increasing solids content. Above a critical value, the viscosity increases rapidly to a limiting point at a volumetric concentration of ca. 40 % solids for all suspensions (Fig. 4). Conversely, the *settling rate*, which is the reciprocal of stability, decreases rapidly with increasing volumetric solids content for equisized particles (Fig. 5, see next page).

Figure 4. Effect of volumetric solids content on viscosity of three media
• Quartz; × Magnetite; + Ferrosilicon

Figure 5. Effect of volumetric solids content on settling rate of three media
• Quartz; × Magnetite; + Ferrosilicon

The coarser the *particle size* of the medium, the faster the solids settle, producing a less stable slurry but a lower viscosity effect at higher concentration. Conversely, the finer the medium particle size, the more stable is the suspension, although the viscosity effect is higher at higher slurry concentrations.

A more stable, and consequently finer, medium is required in dynamic separation because the higher forces involved increase the tendency of the medium to segregate.

The more difficult the separation, the greater is the necessity to have a stable, low-viscosity medium at the operating density and to minimize variation in the medium density during the process.

Magnetohydrostatic separation , in which the apparent density of a magnetic fluid is controlled by a non-uniform magnetic field, is a potential extension of dense-medium separation. It has been studied in the Soviet Union, Israel, South Africa, Great Britain, and the United States.

5. Testing for Dense-Medium Separation

Complete separation, even of particles very close to the separating density, can be achieved in the laboratory by using true heavy liquids and allowing sufficient time for such separation. The most common heavy liquids used are carbon tetrachloride [*56-23-5*] ($\varrho = 1590\,kg/m^3$), 1,1,2,2-tetrabromoethane [*25167-20-8*] ($\varrho = 2970\,kg/m^3$), and thallium malonateformate (Clerici's solution) ($\varrho = 4200\,kg/m^3$). All can be diluted to the desired density, the first two with white spirits or acetone, the last with water. Both cost and toxicity increase with increasing density.

Sequential heavy-liquid separation, in which successive separations occur in a series of liquids of increasing (or decreasing) density, generates either washability curves or partition curves.

A *washability curve* is used to determine the response of an ore to gravity separation. A typical set of curves is shown in Figure 6. These curves allow prediction of the mass and assay of the sink and float; the anticipated recovery at any predetermined density of separation; and the ease or difficulty of the separation proposed. Alternatively, the curves can be used to determine the density of separation required to achieve a desired weight split, product assay, recovery, etc.

Figure 6. Typical set of washability curves
a) Cumulative assay of floats; b) Characteristic assay curve; c) Density curve – the weight percent of material reporting to the sinks at the density of separation; d) Cumulative assay of sinks; e) Recovery: density curve – the percent of heavy mineral M reporting to the sinks (i.e., recovery) at the density of separation; f) Grade: recovery curve – the recovery to sinks of heavy mineral M, at a specific assay of the sinks (%M); g) Tolerance curve – the weight percent of material within a specified density range at the density of separation

In the example shown, preconcentration of an industrial mineral (M) is to be carried out at a density of $2640\,kg/m^3$, equivalent to the minimum (point A) on the tolerance curve (g), thereby assuring maximum efficiency of a reasonably difficult separation. At this density, on the line AB, the weight split is 68 % to sinks, equivalent to a floats assay of 0.3 % (point C) and a sinks assay of 5.1 % (point D). Line DE then shows that recovery of M is 93 % (point E).

Partition curves are used to determine the efficiency of a particular separation process [6].

They are constructed by carrying out sequential heavy-liquid analyses of both products from the separation, and then plotting at each density the proportion of the calculated feed that reports to the sinks or floats. A typical partition curve is shown in Figure 7.

Figure 7. Partition curve

The separating density, σ_{50}, is the density at which a particle has an equal chance of sinking or floating or, conversely, at which it has an equal chance of being misplaced. This is equivalent to the 50 % point, M, on the partition curve. A perfect separation is represented by the vertical line AMB, i.e., all lighter material floats and all heavier material sinks. The actual separation is represented by the curve CMD. The difference between this curve and the vertical represents the amount of error of separation; hence, the total shaded area is the *error area*.

The most common guide to efficiency of separation is the *probable error* E_{p}. This is defined as half the differential in density between the 25 and 75 % partition coefficients on the partition curve:

$$E_{\mathrm{p}} = 0.5\,(\sigma_{75} - \sigma_{25})$$

When plotted on probability paper, the partition curve can approximate a straight line. However, significant "tails" occur at the top and bottom of the line. Modern computer-modeling techniques permit the shape of the generated curve to be described mathematically, although the model most likely to fit the data is still in question [7]. The partition curve, error area, probable error, the computer-generated curve can be used not only to monitor plant performance and acceptance testing, but also to design and predict dense-medium circuit operation. By starting with washability data generated as described earlier and applying the partition coefficients, related to E_{p} (which are known for a specific separator), the partition curve, and hence the characteristics of both products from the separator, can be predicted. A typical predicted separation of coal is shown in Table 1. In this example, at a cut point of 1600 kg/m^3 coal can be obtained with 5.59 % ash and a yield of >70 %.

Dense-medium separation processes have been modeled for many years by means of washability data, because separation is almost entirely dependent on the relative density of particles and medium. Recently, considerable developments have been made in the use of washability data to model most other types of gravity concentration devices; hence, the importance of heavy-liquid analysis in industry is growing.

Table 1. Anticipated separator results in treating any coal of size range 1.5 to 0.5 cm in the same DMS unit at density 1600 kg/m^3

Liquid density, kg/m^3	Heavy-liquid test on head sample of a raw coal			Partition coefficient at assumed cut point $d = 1.6$	Calculated sink–float analysis for separator					
					Clean coal (floats)			Rejects (sinks)		
	wt %	% ash	ash units		wt %	% ash	ash units	wt %	% ash	ash units
Floats 1300	52.8	2.6	1.373	100.0	52.80	2.6	1.373		2.6	
1300 – 1400	12.3	8.7	1.070	96.5	11.87	8.7	1.033	0.43	8.7	0.037
1400 – 1500	4.2	18.8	0.790	84.5	3.55	18.8	0.667	0.65	18.8	0.122
1500 – 1600	2.1	30.0	0.630	63.0	1.32	30.0	0.396	0.78	30.0	0.234
1600 – 1700	2.9	39.4	1.143	34.5	1.00	39.4	0.394	1.90	39.4	0.749
1700 – 1800	1.0	47.1	0.471	13.3	0.13	47.1	0.061	0.87	47.1	0.410
1800 – 1900	1.1	53.6	0.590	4.0	0.04	53.6	0.021	1.06	53.6	0.568
1900 – 2000	1.0	60.2	0.602	0.5	0.01	60.2	0.006	0.99	60.2	0.596
Sinks 2000	22.6	85.1	19.233			85.1		22.60	85.1	19.233
Total	100.0	25.9	25.902		70.72	5.59	3.951	29.28	75.0	21.949

Within a few years, sufficient data will likely be available for design of complete gravity concentration circuits by computer.

1. Introduction

General Aspects. Flotation is one of the well-established physicochemical separation processes, widely applied in mineral concentration and recovery operations; other applications include water treatment and purification, the recycling of secondary materials, and the recovery of ionic and colloidal materials from aqueous solutions.

Various forms of this process are known as froth flotation, ion flotation, precipitate flotation, piggyback flotation, flotoflocculation, skin flotation, column flotation, and two-liquid flotation [1–8]. Gamma flotation is based on the control of liquid – vapor interfacial tension to facilitate the particle – bubble adhesion process [9].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b02_23

Because most flotation processes are applied with water as the principal liquid, and the widest area of applications is in the field of mineral processing, mostly systems containing water and minerals are discussed here.

1.1. Interfacial Energies and Contact Angle

The flotation process relies primarily on the fact that hydrophilic particles are wetted by water, whereas hydrophobic particles are wetted by oils and air bubbles; therefore, if air bubbles are introduced into an aqueous slurry, the bubbles adhere to the hydrophobic solid particles. As a result, air – solid aggregates are carried to the surface, forming a froth layer; this explains the name froth flotation. The froth layer can be removed manually or mechanically; the result is the separation of hydrophobic from hydrophilic particles. For further information on detergency, see also → Laundry Detergents, Chap. 2.1.

Figure 1. Processes occurring in a flotation cell (Schematic)
A) Flotation cell a) Froth overflow; b) Froth layer; c) Pulp; d) Rotor for pulp agitation
B) Mineralized air bubbles within flotation cell

The principal processes occurring in a slurry-containing vessel known as a *flotation cell* are shown in Figure 1. Equation (1), known as the Young–Dupré equation, and Equations (2) and (3) are used to describe the relationship of physicochemical variables to particle – bubble adhesion.

$$\gamma_{SG} - \gamma_{SL} = \gamma_{LG} \cos\theta \quad (1)$$

$$W = \gamma_{LG}\ (1 - \cos\theta) \quad (2)$$

$$S = \gamma_{SL} - (\gamma_{LG} + \gamma_{SG}) \quad (3)$$

where γ_{SG} = solid – gas interfacial tension, γ_{SL} = solid – liquid interfacial tension, γ_{LG} = liquid – gas interfacial tension, θ = contact angle, S = spreading coefficient for air on solid, and W = work of adhesion. For particle – bubble adhesion the conditions $W > 0$, $S > 0$, and $\theta > 0$ are satisfied.

Figure 2 describes the mechanical equilibrium among the three interfacial tensions indicated as vectors applied to point C, known as the three-phase contact point; the contact angle θ is measured in the liquid phase. The two variables $\cos\theta$ and γ_{LG} are readily accessible by experiment. Contact angles on minerals in various media are given in Table 1. The significance of the contact angle arises from the fact that it is a measure of surface wettability; $\theta > 0$ indicates a hydrophobic solid. Contact angle values of $\theta > 10°$ usually indicate that particles can form bubble – particle contacts strong enough to resist turbulence in a conventional flotation cell, enhancing the probability of flotation as decribed in Chapter 4.

Table 1. Contact angles of solids in water and various aqueous media

Solid	Contact angle (degrees)	Solution conditions
Colemanite	43	5×10^{-3} M oleate ∗ solution
Copper metal	93	in 50 mg/L oleate ∗ solution
Fluorite	91	in 10^{-5} M oleate ∗, pH = 8.1

Figure 2. Equilibrium contact angle
a) Captive bubble in water; b) Hydrophobic solid
$\mathrm{Cos}\theta = \frac{\gamma_{SG} - \gamma_{SL}}{\gamma_{LG}}$

1.2. Hydrophobic and Hydrophilic Solids

Although most naturally occurring minerals are hydrophilic, some are hydrophobic. Examples of the latter include graphite, sulfur, antimonite (Sb_2S_3), molybdenite (MoS_2), talc, and high-rank coals such as anthracite. Many polymers, such as Teflon and Nylon, are also hydrophobic.

Hydrophilic materials can be made hydrophobic by the adsorption of chemicals. For example, calcite ($CaCO_3$) can be readily made hydrophobic by treating it with low concentrations of sodium oleate ($C_{17}H_{33}COONa$). Silica (SiO_2) can be made hydrophobic by treatment with dodecylamine ($C_{12}H_{25}NH_2$). A solid made hydrophobic by chemical treatment can revert to the hydrophilic state on further chemical change. For example, galena (PbS), in contact with 25 mg/L potassium ethyl xanthate (potassium *O*-ethyldithiocarbonate) [*140-89-6*] (C_2H_5OCSSK) solution, is hydrophobic at pH below 10.8, but hydrophilic at higher pH. Teflon is highly hydrophobic in most aqueous media, but behaves like a hydrophilic solid if the surface tension is reduced below 20 mN/m by the addition of methanol [10]. Chemicals used to affect the hydrophobic – hydrophilic properties of solids are known as flotation reagents.

2. Flotation Reagents

2.1. Functional Classification of Flotation Reagents

Collectors. These are used primarily to make solids hydrophobic and promote adhesion to air bubbles or oil droplets. Common examples are fatty acids, sulfonates, xanthates (dithiocarbonates), amines, and dithiophosphates.

Frothers. Frothers promote the formation of a metastable froth phase that facilitates the removal of particles carried by air bubbles to the top of the flotation cell. They also reduce the induction time; that is, they allow colliding particles and bubbles to establish contact more rapidly. The usual induction times in sulfide flotations are of the order of milli- or microseconds [12]. Examples of frothers are pine oil, long-chain alcohols, and polyoxypropylene derivatives.

Auxiliary Reagents. These reagents include *depressants,* which are used to prevent solids from becoming hydrophobic, and *activators*, which promote the adsorption of reagents onto selected solids. For example, high pH impedes the flotation of sulfide minerals by xanthates. Thus, reagents used to increase pH, e.g., NaOH or $Ca(OH)_2$, would be depressants in this context. Sulfide ions similarly impede the flotation of sulfides in the same system, and Na_2S used as a source of sulfide ions would act as a depressant. Other depressants include starch and quebracho.

On the other hand, sphalerite (ZnS) does not readily become hydrophobic in the presence of xanthates unless copper (II) ions are introduced into the aqueous pulp. In this case $CuSO_4$, used to supply copper (II) ions, is an activator. Other examples of activation are provided by divalent ions such as barium or calcium in the flotation of silica by fatty acids. In this case, silica is inert to these reagents unless a divalent cation is introduced into the pulp at alkaline pH. Thus, $CaCl_2$ or $Ba(NO_3)_2$ used as sources of these divalent cations and NaOH used to raise the pH would be activators of silica for flotation by fatty acids. The terms *collector* and *frother* do not precisely describe the action of such reagents in all systems.

Although oleic acid acts primarily as a collector in the flotation of solids such as scheelite ($CaWO_4$) it also exhibits excellent frothing properties when present in sufficient quantities. On the other hand, nonanol [*143-08-8*], a well-known frother, is the sole reagent required for the flotation of talc or high-rank coals, where it acts simultaneously as frother and collector. The same is true for activators and depressants. For example, sodium sulfide was cited previ-

ously as a depressant for sulfide minerals in the presence of xanthate reagents. In fact, heavily oxidized (tarnished) sulfide minerals are treated with sodium sulfide before the introduction of xanthates for flotation, making Na_2S an activator in this type of flotation pulp (see Fig. 3).

Figure 3. Activation Processes

2.2. Chemical Classification

Flotation reagents may be inorganic or organic. The former are largely used as auxiliary reagents (Table 2), whereas the latter (Tables 3 and 4) fall into all categories of the functional classification. The organic reagents can be classified as follows:

Polar:
- anionic: polar group is an anion, e.g., oleate, $CH_3(CH_2)_7CH{=}CH(CH_2)_7COO^-$
- cationic: polar group is a cation, e.g., RNH_3^+
- amphoteric: anionic or cationic, depending on pH, e.g., alkylaminocarboxylic acids, $RNH(CH_2)_xCOOH$
- nonionic: polar group is not ionized, e.g.,*n*-hexanol, $CH_3(CH_2)_4CH_2OH$

Nonpolar: e.g., saturated hydrocarbons

Table 2. Inorganic auxiliary flotation reagents

Compound	Composition	Common Applications
Lime	CaO	pH regulator, depressant
Sodium carbonate (soda ash)	Na_2CO_3	pH regulator, dispersant
Sodium hydroxide (caustic soda)	$NaOH$	pH regulator, dispersant
Sodium sulfide	Na_2S	sulfide depressant and ore sulfidizer
Sodium bisulfide	$NaHS$	sulfide depressant and ore sulfidizer
Sulfuric acid	H_2SO_4	pH regulator
Sodium cyanide	$NaCN$	sulfide depressant
Calcium cyanide	$Ca(CN)_2$	sulfide depressant
Sodium dichromate	$Na_2Cr_2O_7$	PbS depressant
Cupric sulfate	$CuSO_4$	ZnS, FeAsS, Sb_2S_3 activator
Lead acetate	$Pb(CH_3COO)_2$	Sb_2S_3 activator
Sodium ferrocyanide	$Na_4Fe(CN)_6$	depressant in Cu – Mo sulfide circuits
Potassium permanganate	$KMnO_4$	FeS_2 depressant in FeAsS flotation
Sulfur dioxide	SO_2	activated ZnS depressant
Sodium thiosulfate	$Na_2S_2O_3$	SO_2 source in acid circuits
Sodium silicate	Na_2SiO_3	siliceous gangue dispersant
Sodium fluosilicate	Na_2SiF_6	depressant in iron-flotation circuits
Sodium polyphosphates	e.g., $(NaPO_3)_6$	dispersant
Sodium fluoride	NaF	activator in silicate flotation
Nokes reagent	complex mixture of P_2S_5, As_2O_3, Sb_2O_3, NaOH, etc.	general depressant in molybdenite flotation circuits except for MoS_2

Organic flotation reagents are also classified by functional group, including fatty acids, carboxylic acids, thiols, xanthates, sulfates, sulfonates, and amines.

Table 3. Organic reagents commonly used as flotation collectors

Compound	Active component(s)	Area of application
Primary amine salts	$RNH_3^+Cl^-$	silica, silicates, sylvite
Quaternary ammonium salts	$RN(CH_3)_3^+Cl^-$ $R = C_{10}-C_{16}$	silicates, oxides, clays
p-Tolylarsonic acid		cassiterite
Sodium salts of carboxylic acids[a]	RCOONa	oxides, carbonates, apatite, iron ores, chromite, scheelite
Alkyldithiocarbamates		sulfides, metallic minerals
Dixanthogens		sulfides, metallic minerals
Hydrocarbon oils[b]	C_nH_{2n+2}	coal, molybdenite, colemanite with sulfonates
Sodium alkylhydroxamates		iron ores, wolframite, cassiterite
Naphthenic acids		fluorapatite, colemanite
Oximes		chrysocolla, cassiterite
Alkylsulfates and -sulfonates	$R-O-SO_3^-\ M^+$ $R-SO_3^-\ M^+$	iron ores, beach sand cleaning, borates, carbonates, fluorite
Sodium 2-(Methyloleylamino) ethylsulfonate	$C_{17}H_{33}-N(CH_3)-CH_2CH_2SO_3Na$	celestite
O-Ethyl isopropyl thionocarbamate		copper sulfides
Thionocarbanilide		sulfide minerals
Alkyldithiocarbonates (xanthates)	$R-O-C(=S)-S^-Na^+(K^+)$	sulfide minerals, gold
Xanthogen formates[c]	$R-O-C(=S)-S-C(=O)-OR$	sulfide minerals
Dialkyl-dithiophosphates[d]		sulfide minerals, native gold, copper

[a] R may be saturated or unsaturated. [b] Vapor oils, kerosene, fuel oils. [c] Trade name: Minerec. [d] Trade name: Aerofloat.

Table 4. Organic chemicals used in flotation as depressants, slime depressants, and flocculants

Common name	Active components	Application
Sodium isopropyl-naphthalene sulfonate Trade name: Aerosol OS		wetting agent, defoamer, dispersant, emulsifier
Sodium dioctylsulfo-succinate Trade name: Aerosol OT		wetting agent, defoamer, dispersant, emulsifier
Poly(ethylene oxide)		flocculant, dewatering aid
Sodium polyacrylate		flocculant, dewatering aid
Starch		slime depressant, iron ore flocculant, slime control agent
Tannic acid		depressant for fluorite, carbonates, and non-sulfides
Quebracho (trade name) extracted from shinopsis trees	 Quinic acid [77-95-2] Shikimic acid [138-59-0] Gallic acid [149-91-7]	depressant for carbonates, fluorite, and nonsulfides
	 Flavone [525-82-6] Coumaran [496-16-2] Catechin [154-23-4]	

Figure 4. Micelle formation

The following organic reagents are commonly used as flotation frothers:

Long-chain aliphatic alcohols $CH_3(CH_2)_nCH_2OH$, $n = 3–6$

Camphor oil
Active component:
Safrole [*94-59-7*]

Dimethyl phthalate [*131-11-3*]

Dimethylphenylcarbinol
(2-Phenyl-2-propanol) [*617-94-7*]

Eucalyptus oil
Active component:
cineole [*470-82-6*]

Methylisobutylcarbinol (MIBC)
(4-Methyl-2-propanol) [*108-11-2*]

Poly(ethylene glycol)
[*25322-68-3*]
$R(OC_2H_4)_nOC_2H_4OH$, $n = 2–5$

Poly(propylene glycol)
[*25322-69-4*]
$H(OC_3H_6)_nOH$, $n = 2–5$

Poly(propylene glycol),
monoalkylether
Trade name: Dowfroth 250
[*37286-64-9*]
$R(OC_3H_6)_nOH$, $n = 2–5$,
$R = CH_3, C_4H_9$

Triethoxybutane
(2,2,3-Triethoxybutane)
[*38620-87-0*]

2.3. Surface and Solution Chemistry

2.3.1. Solubility

Inorganic reagents used in flotation are always highly soluble in water whereas organic reagents may not be. Nonpolar oils, for example, are insoluble in water and must be added to the flotation cell or the preceding conditioning tank, at high shear created by intense agitation of the pulp. Alternatively, these reagents can be prepared as emulsions or sometimes dissolved in an alcohol such as methanol before addition to the flotation system. Straight-chain alcohols containing more than eight carbon atoms are insoluble in water and are used as frothers.

Most ionic or polar flotation reagents are sufficiently soluble in water. Solubility is limited mainly by the tendency of such compounds to form molecular aggregates in the aqueous medium known as micelles when present in high concentrations (Fig. 4, see previous page). The concentration at which micelles form is known as the *critical micelle concentration* (cmc).

2.3.2. Surface Activity

The ability of reagents to alter the liquid – vapor interfacial tension, γ_{LG}, of aqueous solutions is called surface activity (see also → Surfactants). For example, although the surface tension of distilled water is about 72 mN/m at room temperature, the introduction of a flotation reagent such as sodium dodecyl sulfate at a concentration of 0.005 mol/L reduces this value to 48.5 mN/m. Such organic reagents contain two chemical groups: a nonpolar moiety, usually a saturated hydrocarbon, and a polar moiety, which may be ionic (e.g., $-COO^-$, $-SO_3^-$, $-SO_4^-$) or nonionic (e.g., $-OH$, $-NH_2$, $>C=O$).

The quantitative relationship between the concentration of an amphipatic molecule and its effect on the surface tension at concentrations below the cmc is described by the Gibbs adsorption equation:

$$\frac{d\gamma_{LG}}{dC} = -\Gamma k \frac{T}{C} \tag{4}$$

where γ_{LG} = solution surface tension, C = equilibrium concentration of surfactant in solution, k = Boltzmann constant, Γ = surface excess concentration of surfactant measured in quantity per unit area (e.g., molecules/cm^2), and T = temperature.

Based on Equation (4), the variation of solution surface tension can be discerned to be as shown in Figure 5, which predicts that some substances ought to increase surface tension, creating a surface deficiency, as opposed to surface excess concentration. This condition is met by a number of inorganic compounds shown in Figure 6.

Not all amphipatic flotation reagents exhibit pronounced surface activity, as demonstrated by

Figure 5. Variation of solution surface tension by solutes according to the Gibbs adsorption equation (Schematic)
A) Effect of organic surfactants on γ_{LG} and Γ. Condition of surface excess concentration
B) Effect of inorganic solutes on γ_{LG} and Γ. Condition for surface deficiency.
γ_{H_2O} = Surface tension of pure water; γ = Surface tension of solution; Γ = Surface excess concentration

Figure 6. Compounds that lower the surface tension of water are not necessarily surface active, although their structures may indicate amphipatic properties. Short-chain alcohols, acetone, and simple ethers fall into this category (see Fig. 7 on top of next page).

2.4. Interactions between Flotation Reagents and Solids

As a general rule, for alteration of the hydrophobic – hydrophilic properties of solids in a flotation pulp, adsorption or desorption at the surface is a prerequisite. Thus, for a solid to become hydrophobic or hydrophilic it must first take up ions or molecules from the medium or release them into it. Alternatively, a solid made hydrophobic by the adsorption of a reagent changes only by the action of other species which alter the surface properties. This may or may not require the desorption of the species originally present. For example, at a given pH, a given sulfide mineral requires a minimal concentration of flotation collector before stable bubble – particle contact (flotation) can occur [8] (Fig. 8, see next page).

Figure 6. Effects of inorganic salts and organic flotation reagents on the surface tension of water
a) Sodium hydroxide [a]; b) Sodium chloride [a]; c) Potassium ethyl xanthate [b] d) Polyoxyethylene *n*-decanol with 30 ethylene oxide groups [b]; e) Cetyltrimethylammonium bromide [c]; f) Sodium oleate [d];
[a] Drawn from data in [13]. [b] With permission from [14]. [c] Drawn from data in [15]. [d] Redrawn from data in [16].

Silica, treated with trimethylchlorosilane ($Si(CH_3)_3Cl$) shows hydrophobic – hydrophilic transitions that depend on time, pH, and temperature [17]. In all the experimental cases reported for this system, whether the solid was hydrophilic or hydrophobic, the organic reagent was present at the solid surface. The variation of hydrophobic – hydrophilic properties was attributed to the tenacity of the aqueous layer at the solid – liquid interface; the desorption of species that confer hydrophobic characteristics is not always essential for a solid to exhibit hydrophilic properties.

Figure 7. Surface tension of aqueous solutions of acetone and methanol
a) acetone; b) methanol

Naturally hydrophobic solids need to be considered a special case of this general rule, because they may require no surfactant uptake from the medium to become hydrophobic, but can be made hydrophilic by adsorbed reagents. For example, most wetting agents, e.g., Aerosol OT, (sodium dioctylsulfosuccinate) [*577-11-7*], eliminate the natural hydrophobicity of graphite.

2.4.1. Adsorption – Desorption of Inorganic Reagents

In general, the chemical reactions of inorganic flotation species in aqueous solution can be described in terms of solubilities. The classical equilibrium constant (solubility product) applies:

$MA_2 \rightleftharpoons M^{2+} + 2\,A^-$ (5)

$$K_{sp} = [M^{2+}]\,[A^-]^2 / [MA_2] \qquad (6)$$

where M^{2+} indicates the cation (metal) concentration in solution, A^- the anion concentration, and K_{sp} the solubility product. Figure 9 shows the relationships of hydrolysis and precipitation that occur in the aqueous phase for various ions

in accordance with the solubility product principle. Traces of ions or their hydrolysis products many play important activator roles in flotation [20].

2.4.2. Adsorption – Desorption of Organic Reagents

Organic reagents and solids suspended in a flotation pulp interact by one or more of the mechanisms given below. Some processes, such as hydrogen bonding, are also important in the solubilization of polar substances in aqueous media.

Hydrogen Bond Formation. This bond (strength ca. 21 – 29 kJ/mol), usually associated with the physical properties of ice and water, is favored when a group contains hydrogen attached to a highly electronegative element such as F, O, S, or N. Thus, the adsorption of an amide group, present in proteins or nonionic polyacrylamide (a depressant), on fluorite or silica is due to this bond [24, 25]. The interaction of elemental sulfur and alcohols probably also takes place by hydrogen bond formation.

Electrostatic Interactions. Such interactions are nonspecific, occurring between groups that carry electrostatic charges of opposite sign. Bond formation occurs by charge attraction. A typical example in flotation systems is the adsorption of amines that carry cationic polar groups on silica, which carries a net negative electric charge at $pH > 2$. Many treatments of reagent – solid interactions in flotation systems tend to exaggerate the importance of electrostatic interactions, overlooking other mechanisms.

Chemical Bond Formation. Chemical bonds are characterized by their strength (typically greater than ca. 42 kJ/mol) and usually lead to the formation of saltlike structures at solid – liquid interfaces. A surface compound is not necessarily identical to a compound formed in the bulk of the solution [26, 27]. Examples of such bonds include the interaction of fatty acids, which carry the polar carboxylate group ($-COO^-$), with sparingly soluble solids such as calcite ($CaCO_3$) or fluorite (CaF_2). Infrared spectroscopy shows that the calcium oleate formed by the interaction of oleic acid with calcite or fluorite is not identical to the calcium salt of oleic acid, $Ca(C_{17}H_{33}COO)_2$, obtained from $CaCl_2$ and sodium oleate [28].

Hydrophobic Bonding. Association of the hydrocarbon ends of amphipatic substances leads to the formation of *micelles* (Sect. 2.3.1). Similarly, many saturated hydrocarbons, such as kerosene or fuel oils, are readily adsorbed on naturally hydrophobic solids, e.g., graphite or freshly cleaved bituminous coal. Such interactions are mainly a result of London – van der Waals forces. Furthermore, the hydrocarbon ends of surfactants, such as dodecylbenzenesulfonate, and dodecylbenzenesulfate, associate at the solid – liquid interfacial region, resulting in low-energy structures known as hemimicelles [29].

The strength of association is a function of the hydrocarbon chain length and is of the order of 1 kT per $-CH_2$-group (where k = Boltzmann constant and T = temperature). The unique bond that leads to such adsorptions and molecular associations is called the *hydrophobic bond*. Although the term has been criticized [30], it has been generally accepted.

Multiple Dipole Interaction Bonds (Crystal-field Interactions). The adsorption of tannins (depressants in flotation) or polyacrylamide on fluorite has been attributed to the formation of a bond in which an active group of the reagent is held in the crystal field of the adsorbing solid [31]. Little information on such bonds is available.

Collector Fitting into Solid Lattices. The separation of similar salts, such as NaCl and KCl, by the use of amines is a well-established industrial practice. Although a number of mechanisms have been suggested for the selective interaction between KCl and primary amines, the most widely accepted is that the amine fits into spaces on the KCl lattice vacated by K^+ because the ionic sizes of $-NH_3^+$ and K^+ are comparable. Thus, KCl is made selectively hydrophobic, whereas NaCl is not (Fig. 10).

In many systems more than one mechanism may act simultaneously and synergistically. The

term adsorption is used here for the accumulation of a dissolved species on a solid particle. The term sorption is preferred by some authors. The terms physical adsorption or physisorption and chemisorption are also used to distinguish between bonds with strengths less than 20 kJ/mol and those greater than 42 kJ/mol, respectively.

B) Sodium chloride (NaCl)
a) Cl^- b) NH_3^+ ; c) K^+ ; d) Na^+

3. Electrical Phenomena

The main phenomena to be considered in this connection are those associated with the solid – liquid interfacial region. On contact of the solid with the aqueous medium, ionization, ion dissolution, or ion adsorption occurs, resulting in charging of the particle surface. Hydrolysis in the aqueous medium may also alter the character of the ionic species passing into it. The predominant phenomena here relate to the fact that cations are hydrated more than anions and that thermal energy promotes ion mobilization in the system. Ruptured bonds and the lattice parameters also affect the properties of the solid – liquid interface. The cleavage of fluorite, graphite, and chalcopyrite are shown in Figure 11.

Within short periods of contact, a double layer (usually referred to as the electric double layer), consisting of the charged surface of the solid and counter ion, is established. Although earlier theories considered this charge arrangement to be in the form of a simple plate capacitor, colloid science showed that the double layer

Figure 11. Crystal structures and mode of cleavage of minerals

C) Chalcopyrite ($CuFeS_2$) which cleaves irregularly, sometimes at the (011) plane
a) Copper; b) Iron; c) Sulfur

consists of a surface with fixed charge whereas the ionic cloud countering it is diffuse [33]. The overall system, consisting of the solid and the ionic medium surrounding it, conforms to the principle of electroneutrality.

Zeta potential is widely used to describe the role played by the electrical double layer in flotation. It corresponds to the potential that exists at the so-called shear plane, which is created when a charged particle moves under the influence of an external electric field.

Zeta potential can be measured by electrophoresis, sedimentation potential, streaming potential, and electroosmosis. In the first two of these methods the shear plane is created by the motion of the particle; in the other two, the particle (more precisely, a porous bed consisting of many charged particles) is fixed [34, 35]. Equation (7) correlates the zeta potential with the electrophoretic mobility of the particles under the influence of an external electric field:

$$\zeta = \frac{4\pi\eta}{\varepsilon}\frac{V_e}{E} \tag{7}$$

where

ζ = zeta potential
η = viscosity of the aqueous medium
ε = dielectric constant
V_e = electrophoretic velocity of particle
E = electric field between electrodes applying the field

At 25 °C and $\eta = 0.895$ mPa · s, Equation (7) reduces to

$\zeta = 12.8\, V_e = 12.8\, u$ where u = electrophoretic mobility.

The significance of the zeta potential becomes apparent where electrostatic interactions play a major role in flotation reagent adsorption, as shown in Figure 12. The condition at which $\zeta = 0$ is known as the isoelectric point (iep), sometimes, less accurately, the zero point of charge (zpc). In principle, although an iep can be defined for each solid for numerous conditions, the variable most frequently used to describe the ionic conditions at which iep occurs is pH.

Adsorption mechanisms correlate with zeta potential; that is, physical adsorption affects the magnitude of the zeta potential. A change of sign in the presence of an appropriate concentration of adsorbate (see Fig. 13) is taken as an indication of a chemisorption-type reagent uptake [38]. As seen from Figure 13, the iep does not necessarily indicate zero potential at the surface of the particle, only that the potential at the shear plane is equal to zero.

Figure 12. Relationship between iep and flotation properties of goethite (FeO (OH)) [36]
● = Sodium dodecyl sulfate or -sulfonate; ▲ = Dodecylammonium chloride; ◇ = iep
∗ Courtesy USBM; zeta potential measurements made in 10^{-4} M NaCl; note that minimum flotability occurs at the pH of iep and anionic reagents act as collectors at $\zeta > 0$ whereas cationic reagents collect goethite at $\zeta < 0$.

Figure 13. Representation of the fact that zero zetapotential does not necessarily indicate zero surface potential (ψ^o) [35, p. 221]
Dashed line = Inner Helmholz plane; wiggled line = Shear plane
∗ Although ψ_1^o and ψ_2^o are positive and ψ_3^o is negative, all conditions indicate $\zeta = 0$; inner Helmholz plane passes through the centers of unhydrated, specifically adsorbed ions.

Depending on the mechanism of reagent–solid interaction, many systems exhibit correlations between system variables and zeta potential (Fig. 14).

4. Bubble – Particle Interactions

The ultimate objective of a flotation process is the selective removal of solid particles from the aqueous medium, which is accomplished by the adhesion of air bubbles to the hydrophobic particles. Particle flotability can be treated as a probability [39]:

$$P_f = P_c \cdot P_a \cdot P_s \tag{8}$$

where

P_f = probability of flotation
P_c = probability of particle – bubble collision
P_a = probability of particle – bubble adhesion
P_s = probability of formation of a stable particle – bubble aggregate

In some methods, such as vacuum flotation, where dissolved gases become the bubble source, or in situ bubble-generation processes, where acids generate bubbles of carbon dioxide from carbonate-containing pulp, the probability treatment needs to be modified. Equation (8), however, is widely applied, because most flotation systems rely on extraneously introduced air bubbles. Particle – bubble aggregates are shown in Figure 15.

Figure 15. Different forms of particle – bubble aggregates [7,41]
A) Particle attached to bubble
B) Multiple bubble attached to large particle (common in vacuum flotation)
C) Particle – bubble flocculation in pulps containing fine particles

Solids to be floated carry an aqueous film, which may have a thickness as low as tens of nanometers [40]. The stability of this film determines whether a particle will adhere to a bubble on collision within the slurry: if the film thins, ruptures, and recedes, adhesion is facilitated. The time taken for the film to undergo these processes is known as the induction time.

Film stability has been quantified in terms as disjoining pressure [27].

$$\pi_D = p - p_o \tag{9}$$

$$\gamma = \gamma_0 \int_h \pi_D \, dh \tag{10}$$

where

π_D = disjoining pressure
p = pressure inside bubble
p_o = pressure of the bulk of the liquid
γ = specific surface energy of the liquid film
γ_0 = specific surface energy of an infinitely thick film of the same liquid

The conditions for film stability are shown in Figure 16.
For stable films: $\left(\frac{\partial \pi_D}{\partial h}\right)_T < 0$
For unstable films: $\left(\frac{\partial \pi_D}{\partial h}\right)_T > 0$

Figure 16. The concept of disjoining pressure [40]
A) Schematic representation of a disjoining film between a particle and a bubble
B) Relation of film stability to disjoining pressure
a) Stable film; b) Metastable film; c) Unstable film

Disjoining pressure depends on the summation of electrical double-layer effects (π_E), solvation effects (π_s), and London – van der Waals forces (π_v); i.e., $\pi_D = \pi_E + \pi_s + \pi_v$, as well as on the heterogeneity of the solid surface [42]. The role of frothers is to make π_D more positive, i.e., reduce film resistance to rupture.

5. Flotation Processes

The phenomena described so far relate to the froth flotation process. The following variations and techniques are also used:

Collectorless flotation:
froth flotation using the natural hydrophobicity of some minerals

Two-liquid flotation:
variant of froth flotation, using oil droplets instead of air bubbles and an oil layer instead of froth

Column flotation:
variant of froth flotation, employing columns 3 – 9 m high with 0.3 – 1.5 m cross-section

Microbubble flotation:
variant of column flotation, employing bubbles 10 – 50 µm in diameter

Dissolved-air flotation:
air bubbles are generated by applying vacuum to air-saturated slurries

Gamma flotation:
liquid – vapor surface-tension control is used to separate hydrophobic particles

Piggyback flotation:
also known as carrier flotation: uses the mutual coagulation of solids; when one is floated, the other (usually more difficult to float on its own) is also collected

Skin flotation:
hydrophobic particles are removed without froth, but at a layer approximately one particle thick

5.1. The Gamma Flotation Process

The gamma flotation process is characterized by emphasis on the control of solution surface tension. The critical surface tension of wetting of solids is based on a plot of the cosine of contact angle θ against the surface tension of the solution in contact with a solid [43]. Each hydrophobic solid exhibits $\cos\theta = 1$ (zero contact angle) at a given solution surface tension as shown in Figure 17. Difficulties in contact-angle measurements on powdered solids, as used in flotation practice, can be overcome by a technique where flotation recoveries are plotted against solution surface tension [10,44,45]. The γ_{LG} at which flotation recovery is equal to zero is taken as the critical surface tension of wetting, γ_c, of the solid under investigation. The two techniques [43–45] are equivalent [10]; the proof of this constitutes an independent demonstration of the thermodynamic basis of the flotation process [46].

Figure 17. Schematic of critical surface tension of wetting by contact-angle measurement

Figure 18 shows the use of critical surface tension differences of two hydrophobic solids by controlling the surface tension of the solution in which they are suspended. This method is called gamma flotation [9]. The value of the process has been demonstrated for a number of flotation systems including oil shale, sulfide

minerals, and others [48–50] (see Figures 19 and 20). Salt flotation, which has been used in coal processing, is a variant of gamma flotation in which the natural hydrophobicity of coal is exploited and the surface tension of the solution is controlled by salts. Figure 6 shows that some

a) NaCl; b) Na_2SO_4
∗ This method is also known as salt flotation [7, p. 338, 339], [13].

Figure 22. System variables that affect the flotation process [9]

salts raise the surface tension of water to values above the usual 72 mN/m. Figure 21 demonstrates the relationship between solution surface tension modified by salts and flotation results obtained with various coals [9].

5.2. Design of Flotation Operations

Flotation testing is generally preceded by geological, engineering, and mineralogical work. The overall flotation system is a complex combination of variables outlined in Figure 22, but

laboratory testing is based on mineral characteristics and reagent properties. Recovery is "the percentage of total values contained in the ore which is recovered in the concentrate"; grade refers to "assay of values in the concentrate." Recovery and grade tend to vary inversely.

Laboratory tests are designed to establish crushing and grinding conditions and optimize such variables as pulp density, reagent addition, pH, and auxiliary reagent concentration before the pilot plant stage. An important laboratory test is the "locked-cycle test", which simulates pilot plant conditions (Fig. 23) [1].

Figure 23. Schematic of locked-cycle test [51]

Flotation machine variables, such as volume, area, throughput, aeration rate, and cell layout are considered at the plant-design stage. Simulation studies using computer modeling techniques have gained increasing acceptance [1, 52]. The final plant layout provides for product handling, filtration, dewatering, tailings disposal, and plant-water recycling.

5.3. Flotation Machines

Flotation machines consist of a chamber (cell) equipped with entry and exit ports and an agitation assembly that keeps the pulp in constant motion during the separation. These machines fulfill the following functions: (1) mixing and agitation of the slurry, (2) aeration and promotion of particle – bubble collisions, (3) formation of a froth layer and its removal for product recovery, and (4) continuous discharge of tailings, consisting of components not collected in the froth layer [53].

The design of a flotation machine (or cell) is largely empirical and aims at maintaining high throughput subject to the previously stated criteria; the Wemco flotation machine is shown in Figure 24. Flotation cells can reach volumes of 20 – 25 m^3 [54]. Figure 25 is an outline of contemporary flotation machine types; Figure 26 shows cell geometries and paddle designs in mechanically agitated flotation machines. Flotation machines used in water treatment are not always mechanically agitated but may rely on the quieter conditions provided by the generation of air bubbles in the system.

∗ With permission [53]

Such methods include vacuum flotation, in which air-saturated water is subjected to a vacuum for bubble generation. Pressure flotation, on the other hand, does not require the application of vacuum, since air bubbles are released after saturation of water under pressure. Electroflotation has also been used to a limited extent. In this method hydrogen and oxygen bubbles are generated by electrolysis [57].

Figure 25. Types of flotation machines, their modes of operation, and representative manufacturers [54–56]

A new version of an old flotation cell has led to the development of column flotation (see Fig. 27) [58–60]. Column cells seem to perform best with highly hydrophobic solids. They are used for the recovery of sulfides and coal, and to recover valuable particles rejected in the tailings of conventional, mechanically agitated, batteries. Column flotation offers the following advantages:

1) reduction of gangue entrainment in froth,
2) increase of bubble residence times in the pulp,
3) improved selectivity,
4) energy economy per unit weight of values recovered, and
5) improved control and instrumentation.

The following relationships are used in the design of flotation machines [56]:

Geometrical
Effective volume: $V \propto L^{n}$ ($n \sim 2-3$)
Froth area: $A \propto L^{2}$
Impeller/tank aspect ratio: $D/L \propto D^{r}$ ($r \sim 0-0.5$)
Impeller speed
Peripheral speed: $S = \pi ND \propto D^{a}$ ($a \sim 0-0.5$)
Power (constant viscosity and density)
Net power consumption: $P \propto N^{3}D^{5}/N^{c}D^{2c}$ ($c \sim 0-0.33$)
Aeration
Air-flow number: $N(Q) = Q/AND \propto D^{f}$ ($f \sim 0$)
Impeller diameter is the parameter of machine size
Geometry: $L \propto D^{1-r}$; $A \propto D^{2(1-r)}$; $V \propto D^{n(1-r)}$
Power: $P \propto D^{(a+1)(3-c)-1}$
Aeration: $Q \propto D^{a+f+2(1-r)}$
Power intensity or specific power:
$P/V \propto D^{(a+1)(3-c)-n(1-r)-1} \propto D^{b}$
Nominal residence time of air:
$V/Q \propto D^{(2-n)(r-1)-(a+f)} \propto D^{q}$

N = Impeller rotational speed in rpm; D = Impeller diameter; L = Tank length. Exponents are experimental parameters characteristic of specific machine design.

5.4. Industrial Applications

Various methods of separation exploit differences in size, relative density, and magnetic and electrostatic properties. Flotation, however, exploits two unique controllable properties of particulates (Table 5): (1) it operates at very fine particle sizes, and (2) it is based on inherent or modified surface properties of solids.

Since its discovery in the late 19th century, the flotation process has been used principally in the minerals industry. At present, it is used to treat several thousand million tonnes of ore annually. Most of the minerals-related applications aim at recovering ore values, rejecting the rest as tailings.

Applications of flotation in the minerals industry are diverse and include recovery of sulfide minerals, upgrading phosphates ores, ash and sulfur removal from coal, separation of soluble minerals such as halite (NaCl) and sylvite (KCl) from each other, and recovery of fine gold [6–8, 61].

Water-treatment applications include the removal of oily components and colloidal matter from industrial waters, water recycling, and the removal of color and metal ions.

Mineral Flotation. Minerals containing valuable elements can be recovered economically by flotation (Table 6) in the following stages:

Crushing and grinding. These steps reduce particle size and mechanically liberate the desired minerals. Some deposits, such as beach sands or placers, do not require crushing, which is usually effected by jaw or gyra-

tory crushers. For grinding, equipment such as ball mills and rod mills is employed.

Classification and sizing. As can be seen from Table 5, the optimal size range for flotation is 10 – 500 µm. Coal particles can be floated at the upper limit, and copper sulfide particles at the lower. Particles of nonsulfide minerals finer than 50 µm, however, interfere with flotation. Such fines are separated by hydrocyclones, sedimentation tanks, and other classification equipment; they are discarded as slimes (Figure 28).

Conditioning. In the conditioning operation the ore powder is slurried with water and flotation reagents, forming the flotation slurry. In the flotation step, air is introduced to transfer hydrophobic particles to a froth layer, which is skimmed away mechanically by paddles.

Figure 27. Pilot plant size flotation column
a) Wash water flow meter; b) Conditioner; c) Valve; d) Concentrate discharge; e) Porous glass diffuser; f) Air regulator; g) Air flow meter; h) Tails discharge

Table 5. Physical properties of particulates and size ranges suitable for separation technology

Physical property	Physical separation technique	Approximate particle size range, mm
Color or radiation	sorting	10 – 100
Size	dry or wet screening	0.01 – 10
Size, shape, density	wet or dry cyclones	0.005 – 1
	sedimentation and hydraulic classification	0.003 – 3
	centrifugation	0.001 – 0.05
Density	heavy media	1 – 10
Size, density	jigging	5 – 50
	tabling	0.005 – 3
Magnetic susceptibility	wet or dry magnetic separation	0.001 – 5
Surface or bulk conduction	electrostatic separation	0.05 – 5
Surface chemistry	flotation	0.001 – 0.5
	spherical agglomeration	0.01 – 0.5
	selective coagulation and selective flocculation	0.05 – 0.001

The solids content of the pulp, known as pulp density, averages 20 – 40 %, but may be 3 – 10 % in some systems, such as coal flotation. In the preparation of potable water, the solids content may be well below 1 %.

The mineral flotation process is carried out in interconnected batteries of flotation cells, where slurry flow occurs by gravity and the level of the slurry is controlled by gates or weirs.

The arrangement of flotation cells, sometimes with intermittent grinding of the products, leads to flotation circuits of which five basic types have been identified [62] (Fig. 29).

5.4.1. Sulfide Mineral Flotation

Sulfide minerals such as those of copper ($CuFeS_2$), lead (PbS), and zinc (ZnS) are commonly found in the same ore. Xanthates (dithiocarbonates) and dithiophosphates are used as collectors in sulfide mineral flotation; frothers include pine oil and synthetic commercial compounds such as Dowfroth 250. Some qualified generalizations apply to sulfide mineral flotation:

1) Xanthates and dithiophosphates are collectors for sulfides.
2) The chemisorption of xanthates and the presence of oxygen are essential for the flotation of sulfide minerals such as galena [63–65].

Table 6. Elements contained in minerals recovered by flotation

Element	Mineral	Composition	Element	Mineral	Composition
Al	bauxite	$Al_2O_3 \cdot xH_2O\,(Fe,Mn,Ti)$	Mn	pyrolusite	MnO_2
Al	kaolinite	$Al_2Si_2O_5(OH)_4$	Mo	molybdenite	MoS_2
As	arsenopyrite	$FeAsS_2$	Na	halite	NaCl
Au	native gold		P	fluorapatite	$Ca_5F(PO_4)_3$
B	colemanite	$Ca_2B_6O_{11} \cdot 5\,H_2O$	S	native sulfur	
Ba	barytes	$BaSO_4$	Si	quartz	SiO_2
C	diamond	carbon	Sn	cassiterite	SnO_2
C	graphite	carbon	Sr	strontianite	$SrCO_3$
Ca	calcite	$CaCO_3$	Th	fergusonite	$(Y,Ce,U,Th,Ca)\,(Nb,Ta,Ti)\,O_4$
Cr	chromite	$FeO \cdot Cr_2O_3$	Ti	rutile	TiO_2
Cu	chalcopyrite	$CuFeS_2$	U	carnotite	$K_2O \cdot 2\,U_2O_3 \cdot V_2O_5 \cdot 2\,H_2O$
F	fluorite	CaF_2	V	vanadinite	$Pb_5ClV_3O_{12}$
Fe	hematite	Fe_2O_3	W	scheelite	$CaWO_4$
Hg	cinnabar	HgS	Y	monazite	$(Ce,Y)\,PO_4$
K	sylvite	KCl	Zn	sphalerite	ZnS
Li	spodumene	$LiAl\,(SiO_3)_2$	Zr	zircon	$ZrSiO_4$
Mg	magnesite	$MgCO_3$			

Figure 28. Characteristics of slimes [7]

This correlates well with the electrochemistry of the system and the stability of species that collect at the solid surface (Fig. 30).

3) Other variables being constant, an increase in chain length for a homologous series of reagents strengthens them as collectors; this rule also applies to other minerals; see Figure 14.
4) At a given constant collector concentration, a critical pH for each sulfide mineral determines the boundary of flotation – no flotation conditions. The ratio of concentration of xanthate to hydroxide for such a critical transition usually conforms to the Barsky relationship: $[X^-]/[OH^-] = \text{constant}$
5) The ions OH^-, S^{2-}, CN^-, $Cr_2O_7^{2-}$ are common sulfide mineral depressants for selectivity control in flotation; Cu^{2+} is an activator for ZnS in flotation by xanthates. Figure 31 is a flow diagram of a sulfide flotation plant.

5.4.2. Nonsulfide Flotation

Nonsulfide ores include those of iron, phosphate, fluorite, magnesite, and beach sand. Some ores may contain sulfur-bearing minerals as secondary components. Collectors in these systems are generally fatty acids and their salts, sulfonates, and sulfates. Amines are also used, especially in iron-bearing ores and in silicate flotation. Figure 32 shows the separation of lead carbonate, barium sulfate, and calcium fluoride in a 100 t/d plant; the main gangue is siliceous material.

Phosphate-ore concentration plant flow sheets are shown in Figures 33 and 34. Their difference lies in the run-of-mine grades and the complexity of gangue minerals.

An interesting application of nonsulfide mineral flotation is the separation of soluble salts from brines (Fig. 35). Primary amines are well-established selective collectors and have long been used in the production of KCl from the Dead Sea. In some cases, clays interfere with

the flotation and need to be depressed by the addition of starch, lignin, or cellulose derivatives.

5.4.3. Coal Flotation

Coal is cleaned by gravity separation to reduce ash and pyrite content [69]. These methods include jigging, tabling, and heavy-media separation. The fines (ca. 400 µm, 35 mesh) are treated by flotation. To liberate ash and sulfur-bearing components, the run of mine coal is sometimes ground to ca. 600 µm (28 mesh) or finer, and the whole mass subjected to flotation without recourse to primary gravity separation. The natural hydrophobicity of freshly ground coal is an asset which minimizes the use of collectors. A small quantity of MIBC or pine oil (50 – 100 g per tonne of mineral) acts as both collector and frother.

On extended storage, or if the coal seam has been in contact with air for geological time periods, coal loses its hydrophobicity and is referred to as "weathered coal". In such cases, MIBC, low pH, and the addition of hydrocarbon oils such as

Figure 33. Flow sheet for phosphate ore flotation in Brazil ∗

∗ The main mineral of value is apatite; the gangue contains barytes, iron oxides, and silicates; fatty acid flotation generates concentrates assaying an average of 36 % P_2O_5, with recoveries of 62 – 63 %; with permission [66].

kerosene or fuel oil make coal matter floatable [42, 70].

Sometimes, pyrite is first removed by conventional sulfide mineral flotation using xanthates as collectors. This is followed by the flotation of coal matter and the rejection of ash-forming materials such as silica, silicates, and carbonaceous shale.

Unlike other minerals, coal exhibits a high degree of variation with respect to origin, age, rank, moisture content, degree of weathering, physical and chemical structure, and nature of gangue. As a result, it is difficult to develop a unified flotation strategy from sample to sample. Even samples of the same origin undergo surface chemical changes to different extents on prolonged storage.

Nonetheless, generalized strategies are possible (Table 7). Figure 36 shows a flow sheet of coal flotation [71].

5.4.4. Flotation of Precipitates and Ions

Precipitate flotation is based on the same principles as mineral flotation. For example, in the preparation of potable water, the adjustment of pH to precipitate ferric ions as hydroxides eliminates most of the iron and colloidal matter by a subsequent flotation step. In this case, the water contaminants render the hydrolysis product sufficiently hydrophobic for bubble – particle adhesion to permit flotation under quiescent conditions.

Alternatively, dissolved ions can be electrostatically attached to selective cations, which in turn can be collected in a foam layer (Fig. 37). The recovery of Au, Pd, Pt, and Ir by such foam fractionation methods, as well as the removal of uranium from aqueous solutions by the use of amines, has been demonstrated [73–75].

Figure 38 shows a foam fractionation (ion flotation) assembly. At times of increasing environmental concern, the removal of heavy metal ions and toxic substances such as PCBs

Figure 34. Flotation flow sheet for Finnish low grade apatite ore ∗ [67]

∗ Gangue minerals include calcite, dolomite phlogopite [$(KMg_3(AlSi_3)O_{10}(OH,F)_2$], and mica.

(polychlorinated biphenyls) seems a promising area for further application of ion flotation and foam fractionation techniques.

5.4.5. Use of Oil Droplets instead of Air Bubbles

Surfaces to which air bubbles can adhere are also readily wetted by hydrocarbon oil droplets in preference to water. This has been demonstrated thermodynamically and experimentally. Although micrometer-size solid particles may adhere nonselectively to air bubbles, the replacement of air by hydrocarbon oils provides better selectivity, as proved experimentally. These considerations have given rise to the development of two-liquid flotation for extraction of finely divided solids into an oil phase (oil extraction) in assemblies similar to those used in conventional flotation technology.

This method has been used for alumina (Al_2O_3), hematite (Fe_2O_3), cassiterite (SnO_2), and artificial diamonds, by first making the powders hydrophobic with an amine or a sulfonate, followed by extraction into an oil phase [76, 77]. The thermodynamics of the system apply equally well to the now well-established process of coal cleaning by oil agglomeration.

6. Future Trends

The decline in the mining and metallurgical industries has shifted emphasis away from conventional flotation technology. Nonetheless, understanding of the fundamentals of flotation is by no means complete and development of sophis-

Figure 35. Potash treatment flow sheet as practiced by the Potash Corporation of Saskatchewan, Canada [68]

ticated instrumentation is leading to combined research on materials science and on surface fundamentals of flotation [78].

As new applications, such as control of the so-called pulp potential, control of redox conditions, E_h, use of critical surface tension of wetting, and flotation of ions and dissolved species, such as toxic and hazardous materials, become more widespread, froth flotation will be employed more and more.

Computer technology and instrumental control now make larger plants possible with higher-grade products and more complete recoveries. Furthermore, pyrometallurgy and hydrometallurgy are now used together with flotation for recovery of metals from slags or melts [79].

The flotation of precious metal-bearing ores and native gold is widely applied despite the apparent fate of sulfide mineral flotation. Less familiar systems such as rare-earth minerals are finding increased interest. Column flotation promises wider application. The custom-design of flotation chemicals is also under development and wider application of flotation in recycling industries is at its early stages.

1. Introduction

Mixing, stirring, and kneading have been used by man since time immemorial in the preparation of food and drink, and belong to the classical unit operations used in the most diverse branches of industry–production of building materials, glass, chemicals, food processing, etc. In the chemical industry, this technology is of special importance: to carry out a chemical reaction, the solutions and mixtures must be prepared in such a way that the reagents have a suitable form for reaction. During the reaction itself, the mixing operation must ensure that the reagents stay in close contact with each other; this is particularly important when the reagents have a different aggregate state.

Table 1. Classification of mixing operations according to the aggregate state of the predominant component

Aggregate state	Operation	Most common mixing equipment
Gaseous *	mixing	mixing chamber, nozzle
Liquid	stirring	stirrer
Paste	kneading	kneader, screw extruder
Solid (granular)	mixing	mixer

* The mixing of gases is treated under → Continuous Mixing of Fluids.

The operations used for mixing must first be classified according to the state of aggregation of the predominant component; as a rule, the resulting mixture has this state, too. From the process engineering point of view, stirring a gas into a liquid is not the same as mixing a liquid into a gas stream. Even the term liquid state must be made more specific, since low-viscosity liquids place drastically different demands on mixing equipment than viscous, pastelike substances. Bearing these considerations in mind, mixing operations can be divided into the groups listed in Table 1.

2. Mixing of Homogeneous Miscible Substances

A mixture that is homogeneous at the molecular level results only when mixing gases or miscible liquids. Here the mixing operation can be divided into two steps: (1) pre-mixing taking place through the large-scale convective transport of eddies and (2) elimination of concentration differences through purely diffusive transport. The former is governed by the physical properties as well as by the type of mixing device and the mixing energy expenditure; it is scale-dependent. The better the pre-mixing, i.e., the smaller the eddies produced, the faster the following mixing process can proceed. The latter is governed by those material properties of the system that influence diffusion (viscosity, diffusion coefficient) and is only rate-limiting if the pre-mixing was not intensive enough. Good mixing devices (nozzles, stirrers causing a pronounced bulk circulation) usually function so well that the process of diffusion has no effect on the homogenization time (no effect of the Schmidt number *Sc* on the homogenization characteristic, → Stirring, Chap. 2.

In the last few years, *micromixing* has received special attention; this refers to the production of extremely small eddies with the purpose of mixing the reaction components as fast as possible. For example, micromixing plays a key role in competitive reactions of the type

$$A + B \longrightarrow C \quad (1)$$
$$A + 2B \longrightarrow D \quad (2)$$

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b02_24

In this case, the selectivity of the desired Reaction (1) can be increased through a fast reduction of the reagent concentrations. If the reaction, however, is of the competitive-consecutive type,

$$A + B \longrightarrow C \quad (3)$$
$$A + C \longrightarrow D \quad (4)$$

then it is also important to avoid backmixing of the reagents with the product C. In such cases a plug-flow reactor is used, and mixing is performed with a nozzle or an in-line mixer.

3. Mixing in Heterogeneous Systems

The main objective of the mixing operation in the spraying of liquids in a gas and in the dispersion of immiscible liquids or gases in a liquid is to create as large an interfacial area as possible. In these operations, however, fine primary droplets or gas bubbles often have the tendency to coalesce; i.e., a part of the work done in forming the interfacial area is wasted. During the production of fine bubbles or droplets in stirred vessels, the size distribution of the bubbles or droplets is the result of a continuous process of dispersion and coalescence.

The*coalescence process* depends to a great extent on the state of flow in the mixing device, thus requiring care in equipment scale-up. To allow reliable conclusions, design guidelines for mixing devices for these operations must be based on experiments in several different scales. The exact physical properties that determine coalescence are still not known: some substances suppress coalescence strongly, even in extremely small concentrations (a few ppm), while others increase the coalescence tendency. Especially in the dispersion of gases in liquids, the coalescence behavior of the system must be determined through appropriate experiments in the laboratory.

4. Mixing of Pastes and Granular Materials

Pastes and powders or granular materials are usually mixed to achieve the best possible blending. Here, however, only a stochastically homogeneous mixture is possible, a mixture that depends strongly on the physical properties of the substances to be mixed (viscosity and rheological behavior for pastes, size and morphology for granular solids). In the mixing of granular materials, *mixture separation,* determined by the state of flow in the device and therefore scale-dependent often presents a problem. Since the sampling, analysis, and the statistical evaluation of experimental data are problematic, there are comparatively few reliable design and scale-up guidelines for these mixing devices. In the future, significantly more intensive research activity in this field is necessary.

1. Stirring Operations, Stirring Vessels, and Stirrer Types

1.1. Stirring Operations

When the liquid component predominates in the mixture (→ Mixing, Introduction), the mixing operation is termed *stirring*, and a stirrer is used to perform it. The following five stirring operations may be defined:

1) Homogenization, i.e., equalization of differences in concentration and temperature
2) Intensification of heat transfer between the liquid and the heat-exchange surface
3) Suspension of a solid in the liquid, or slurry formation
4) Dispersion of two immiscible liquids
5) Dispersion or sparging of a gas in the liquid (gas – liquid contacting)

Homogenization refers to the formation of a uniform phase out of several miscible liquids or to the elimination of concentration and temperature gradients during a chemical reaction in the liquid phase. (In the food industry, the same term is also used for emulsification under extreme shear conditions, e.g., the homogenization of milk.)

Intensification of heat transfer in mixing vessels – especially in highly viscous liquids – can be an important stirring operation, particularly in the case of a strongly exothermic chemical reaction, for example, block polymerization. In this case, stirring aims to reduce the boundary layer at the vessel wall, as well as to provide for the motion of the liquid to and from the heat-exchange surface.

When particulate materials are to be dissolved in a liquid, or when a solid-catalyzed reaction is to take place, the stirrer must make a *suspension* of the particles in the liquid to allow their entire surface to take part in the process. For continuous processes, a quasi-uniform distribution of the solids in the entire liquid volume is required; this allows the solid particles to be transferred from stage to stage together with the liquid (e.g., in crystallization cascades). In this case, the solids are exposed to high mechanical stress, which can cause their abrasion.

In order to enhance mass transfer between two immiscible liquids, the phase with the smaller volume is dispersed in the other, i.e., a *liquid – liquid dispersion* is made. When surfactants are added, a more or less stable emulsion can be produced.

Stirrers are also used to perform gas – liquid contacting to make *gas – liquid dispersions.* The process is also called *sparging.* Different stirring operations must often be performed simultaneously; an example is solid-catalyzed hydrogenation, in which the stirrer must both distribute the gas (hydrogen) in the liquid, as well as suspend the solid catalyst (e.g., Raney nickel).

1.2. Stirring Vessels and Auxiliary Equipment

Mixing operations are mainly performed in agitated vessels, but storage tanks and pipes can also be employed (cf. Section 2.6). The design of mixing vessels is governed by standards (DIN 28 136, ASME Code Section VIII). The interior auxiliary equipment consists of baffles, feed and drain pipes, coils, and probes (e.g., thermometers, level indicators). All of these inserts can affect stirring.

If an axially positioned stirrer is operated in a *vessel without inserts*, the liquid is set into rotation, and a vortex is formed. The vortex can reach the stirrer and cause gas to be entrained in the liquid. This is generally undesirable because it results in an extraordinarily high mechanical stress in the stirrer shaft, as well as in its bearings and seal, due to the absence of the liquid bearing, often leading to the destruction of the stirrer. Even when vortex formation causes no gas entrainment, bulk rotation of the liquid is always undesirable when a two-phase system with different densities is concerned since the centrifugal force counteracts stirring.

Bulk rotation of the liquid in cylindrical vessels is prevented by the installation of baffles. Fully effective baffling is achieved with four baffles having a width of $D/10$ (D = inside diameter of vessel), which are vertically arranged along the entire vessel wall. In order to avoid dead volume behind the baffles, the baffle width is reduced to $D/12$ and they are set at a clearance of $D/50$ from the wall. The baffles are usually attached to the vessel wall by means of welded brackets (Fig. 1 A). In enamel-coated vessels, they are attached to the cover. When this is not possible (glass vessels, wooden vats), they are made in the form of a basket with pressure-fitted rings (Fig. 1 B).

Figure 1. Baffle designs
A) Normal design; B) Design for glass and coated vessels (baffle basket with pressure-fitted ring)

Baffles are not necessary when stirring is carried out in vessels with rectangular cross section

Figure 2. Tube coil designs
A) Spiral coil; B) Meander coils (cooling basket); C) Tube bundles

Figure 3. Common stirrer types

(pits), or when the stirrer is introduced into the vessel laterally. When the stirring is weak, liquid rotation can be prevented even in cylindrical vessels by installing the stirrer off-center and/or at an angle to the axis. In this case, however, uneven mechanical stress in the stirrer shaft must be accepted.

In order to supply or remove large amounts of heat, stirring vessels are equipped with *coils.* A spiral coil (Fig. 2 A) is only effective with stirrers that generate an axial flow pattern, since these produce good liquid circulation between the coil and the wall. In contrast, the liquid circulation produced by radial stirrers is strongly deflected by the spiral coil, so that the flow through the annulus between the coil and wall is insufficient. For these types of stirrers, it is better to arrange the coil vertically along the vessel wall (meander coil, Fig. 2 B). This arrangement does not deflect the radial flow pattern, but prevents bulk rotation of the liquid to such an extent that baffles are often unnecessary. The heat-exchange tubes can also be arranged into bundles and installed instead of baffles (Fig. 2 C).

1.3. Operation of Individual Types of Stirrers

The mixing operations described in Section 1.1 naturally cannot all be performed with a single stirrer type; therefore, a wide variety of stirrers exists. There are stirrers suitable to a specific mixing operation and a given material system. The following discussion is limited to those stirrer types which are most widely used in the chemical industry, and for which established design guidelines exist.

Figure 4. Flow patterns in a baffled tank, generated by an axial-flow propeller and a radial-flow turbine stirrer

These stirrer types are arranged in Figure 3 according to the predominant flow pattern they produce, as well as to the range of viscosities over which they can be effectively used. The flow patterns generated by stirrers causing radial and axial fluid motion are shown in Figure 4.

The *turbine stirrer* (Rushton turbine, six blades on a disk) is the only high-speed stirrer that sets the fluid in *radial motion* or, at higher viscosities, in *tangential motion.* This type is only effective with low-viscosity liquids and baffled vessels. In this case, the diameter ratio D/d (D = vessel diameter; d = stirrer diameter) ranges from 3 to 5. During rotation, the turbine stirrer causes high levels of shear and is well suited to dispersion processes. The *impeller stirrer* was developed for use in enamel-coated vessels, and thus has rounded stirring arms. It is used in conjunction with small clearances from the bottom and with a ratio $D/d = 1.5$, either with or without baffles. It can also operate with strongly fluctuating fill levels (e.g., during vessel discharging) because it mixes even small amounts of liquid very well. The *cross-beam*, *grid,* and *blade stirrers* belong to the group of low-speed stirrer types and are used with $D/d = 1.5 - 2$. They can operate with baffles or, for viscous fluids, without, and are especially well suited to homogenization. As a rule, the low-speed *anchor stirrer* is operated at very small clearances from the wall ($D/d \simeq 1.05$) and is only appropriate for enhancing heat transfer in highly viscous liquids.

The *paddle stirrer* with pitched blades (pitched blade turbine) and particularly the *propeller stirrer* belong to the group of high-speed mixers that generate an *axial flow pattern.* As a rule, both are used with low-viscosity liquids and in baffled vessels. They are well suited to homogenization and suspension of solids. In order to enhance the axial flow component in more viscous media and/or for $H/D > 1$ (e.g., in fermenters; H = liquid height) multistage stirrers with pitched stirring surfaces are required. This category includes the *cross-beam stirrer with pitched beams* and the *MIG* and *INTERMIG* stirrers of the Ekato company, Schopfheim, Germany. These stirrers are operated at low speeds, with $D/d \simeq 1.5$ (with baffles) or $D/d = 1.1$ (without baffles). Mixing operations for these types include homogenization, suspension of solids, and dispersion. The very low-speed *helical rib-*

bon stirrer is used with small wall clearances ($D/d \simeq 1.05$) and operated in such a way that it drives the liquid downwards along the wall. Under these conditions, it is the best-suited of all stirrer types for the homogenization of highly viscous liquids.

In addition to these often used types, a large number of special designs also exists. Of these, only three should be mentioned: the stirrer operating on the rotor – stator principle, the toothed disk, and the hollow stirrer.

In *rotor – stator stirrers* (Fig. 5), the rotor consists of a blade or paddle stirrer enclosed by a ring of baffles (stator). As a result, high levels of shear are exerted on an extremely small volume. When the stirrer consists of a planar *toothed disk* (Fig. 6), the liquid is accelerated radially in a thin ring away from the center, and then quickly decelerated. High levels of shear can thus be achieved, even without a stator ring or baffles. Both of these stirrer types are particularly well suited to emulsification and dispersion over a wide range of viscosities, e.g., in the production of paint pigments.

Figure 5. A rotor – stator stirrer

Figure 6. Disperser disk

In *hollow stirrers*, the stirrer head is hollow and is connected through a hollow shaft to the gas-filled space above the liquid surface. The suction generated behind the stirrer edges during rotation can thus be used to supply a gas to the liquid. As a single unit combining both stirrer and gas supply, hollow stirrers are well suited for enhancing mass transfer in gas-liquid systems. Figure 7 shows the so-called *tube stirrer*, a simple, effective hollow stirrer. All hollow stirrers operate at high speeds and are used in baffled vessels with $D/d = 3 - 5$.

Figure 7. Hollow stirrer (tube type)

1.4. Mechanical Stress Exerted by the Stirrer

A distinction has to be made between the aspects which concern construction of a device and those which are of concern to users of the device. Information on the mechanical forces, which operate on the stirrer, the shaft, the shaft bearings, and the shaft seal, together with the critical stirrer speed etc., can be obtained from the brochures of the stirrer manufacturers. Information on the stress on baffles and on stirrer heads as well on the wear of stirrer heads is summarized in [1]. Here, only the shear stress on the particulate material being mixed is considered. Shear stress can be advantageous, e.g., in dispersion processes in gas – liquid (G/L) and liquid – liquid (L/L) systems. It can, however, also be undesirable, e.g., in many agglomeration and crystallization processes, particularly in biotechnological systems. Mammalian cells, for example, can be destroyed even at low shear forces. The morphological structure of cell clusters, important for product formation in fungal cultures (penicillin and citric acid), can be negatively influenced by

shear forces, as can the biofilm formation of microorganisms and enzymes on solid carriers (immobilization of biomaterial). It is therefore not surprising that an increasing number of papers have been published on this topic in the recent biotechnological literature [1].

It had been found that the destruction of clay flocks, as a representative model system for biological material, depended strongly on the power per unit volume P/V_s (in kW/m$_s^3$) where V_s is the volume swept by the stirrer, $V_s = \pi d^2 h$ (h = stirrer height), assuming that most of the power has been dissipated in this volume [2]. The following correlation has been obtained for six different stirrer types for the flock diameter d_f (μm):

$$d_f = 130\,(P/V_s)^{-1/3} \tag{1}$$

Propeller stirrers need higher rotational speeds than large-surface stirrers (cross-beam or anchor stirrers) to achieve the same P/V values. They therefore produce higher shear rates and should not be used for shear sensitive material.

Equation (1) is consistent with the Kolmogorov's theory of locally homogeneous and isotropic turbulence [1]. In the turbulent flow range, turbulence exists on the micro- and the macroscale. The microscale λ is responsible for the shear stress, which for a particle size, d_p, which is significantly smaller than λ (λ/d_p = 5 – 25), can influence the particle size of the dispersed phase.

According to Kolmogorov the microscale λ of turbulence is described by $\lambda = (\nu^3/\varepsilon)^{1/4}$ (ε is the power consumption per unit mass, $\varepsilon = P/\varrho V$, and ν is the kinematic viscosity of the liquid). The shear condition on a small scale is similar to that on a large scale when P/V, the physical properties (ν) and the geometry are kept constant:

$$\lambda = \left(\varepsilon/\nu^3\right)^{1/4} = \text{idem} \tag{2}$$

2. Homogenization of Liquid Mixtures

2.1. Problem Definition

Homogenization deals with the mixing of miscible liquids to obtain the desired degree of homogeneity, or with the maintenance of homogeneity for the purpose of carrying out a reaction under well-defined conditions. The question here is what type of stirrer and what mixing conditions to adopt, so that the mixing operation can be performed with the minimum effort (inexpensive stirrer, low mixing work). In order to answer this question, the mixing time and power characteristics must be known for the stirrer.

The term *characteristic* means a relationship between dimensionless groups that describes the dependence of a target quantity (mixing time, power, etc.) on geometrical, physical, and process parameters. In terms of fluid mechanics, mixing is a complicated operation. Process-related questions are almost exclusively answered by experiments, which are best evaluated using dimensional analysis. This allows the number of parameters to be reduced, and ensures a reliable scale-up in combination with the theory of models [3] → Scale-Up in Chemical Engineering.

2.2. Mixing-Time Characteristic

2.2.1. Definition and Measurement Method

The mixing time θ is the time required for the mixer to achieve the desired degree of homogeneity. A statement of the mixing time is therefore only meaningful in conjunction with the degree of homogeneity. The most common methods for determining the mixing time are the schlieren method and the chemical decolorization method. In the *schlieren method*, two liquids having different refractive indices are mixed; the complete homogenization of the liquids is indicated by the disappearance of the streaks (schlieren). In the *chemical decolorization method*, the first liquid, which contains one reaction component, is colored with an indicator; the second liquid, containing the other reaction component, is then added as the stirring begins; and the time at which the color disappears is measured. (Common reaction systems: sulfuric acid/alkali solution with phenolphthalein indicator; thiosulfate/iodine with starch indicator.) The degree of homogeneity at the point of decoloration depends on the excess of the added

reaction component (Danckwerts method [4]). The principles and applications of this method are described in [5]. Chemical decolorization methods fail for extremely short mixing times (micromixing). In such cases, a consecutive dye reaction (diazotization) is used instead; the degree of mixing can be determined from the selectivity. Details of both methods can be found in [1] and → Mixing, Introduction.

2.2.2. Mixing-Time Characteristic at $\Delta\varrho \simeq 0$ and $\Delta\nu \simeq 0$

In the homogenization of liquids having the same density ϱ and kinematic viscosity ν, the mixing time θ for a given stirrer type and vessel inserts depends on the speed n, and diameter d of the stirrer. In terms of dimensional analysis, this can be expressed as $n\theta = f\,(Re)$. In this equation, known as the mixing-time characteristic, $n\theta$ represents the mixing number and Re the Reynolds number, $Re = nd^2/\nu$.

Since each mixing-time or homogenization characteristic is only valid for the particular geometry, the dimensional proportions of the stirrer types treated are given in Figure 8.

Figure 9 shows the mixing-time characteristics for these stirrer types as determined by the chemical decolorization method. With an excess of ca. 0.01 N of acid, the decolorization indicated an essentially complete molecular homogenization [6]. Figure 9 allows the determination of the mixing conditions required to achieve a desired mixing time. It provides the number of stirrer rotations ($n\theta$) needed to homogenize the mixture under given flow conditions (Re). Depending on the range of Reynolds numbers, the following stirrers can produce homogenization with the minimum number of rotations: helical ribbon mixer, blade stirrer, and the MIG stirrer, the last two in baffled vessels.

As the ratio H/D increases, the mixing time becomes longer; for a baffled vessel with a cross-beam stirrer, the following relationship is valid over the range $10^3 < Re < 10^5$ [6]:

$$n\theta = 16.5\,(H/D)^{2.6} \tag{3}$$

(The number of stirrer beams is assumed to increase with vessel height in accord with Figure 8 A).

Mixing-time characteristics for 25 % and 10 % deviation from the final mixed state have been obtained by C. J. Hoogendoorn and A. P. den Hartog [7]. Homogenization and power characteristics for enamel-coated stirrers with rounded edges can be found in [8]; a number of other mixer types and insert configurations are treated in [9].

2.2.3. Mixing-Time Characteristic at $\Delta\varrho \neq 0$ and $\Delta\nu \neq 0$

In the homogenization of liquids with different densities and viscosities, coarse mixing is affected by the specific weight difference of the two components, $g\,\Delta\varrho$; however, the elimination of the final concentration gradients takes place under conditions characterized by the properties of the homogeneous mixture, $\bar{\varrho}$ and $\bar{\nu}$. In this case, the mixing time depends on the following parameters: $\theta = f\ (n, d, \bar{\varrho}, \bar{\nu}\ g\,\Delta\varrho)$; in terms of dimensional analysis, this can be expressed as $n\theta = f\,(Re, Ar)$, where $Re \equiv nd^2/\bar{\nu}$ is the Reynolds number and $Ar \equiv d^3\,g\,\Delta\bar{\varrho}/(\bar{\nu}^2\,\varrho)$ the Archimedes number. The mixing-time characteristic of a cross-beam stirrer, as in Figure 8 A, operating in a baffled vessel with $H/D = 1$ is as follows [10]:

$$n\theta = 51.6 Re^{-1}\left(Ar^{1/3} + 3\right) \tag{4}$$

This relationship is valid for $10 < Re < 10^5$ and $10^2 < Ar < 10^{11}$.

2.2.4. Mixing-Time Characteristics in Non-Newtonian Liquids

Mixtures of non-Newtonian liquids are homogenized considerably more slowly than Newtonian liquids in the laminar and transition flow regimes. This is also due to the shear rate field existing in the stirring tank, which causes strong viscosity differences.

In most studies on non-Newtonian liquids carboxymethyl cellulose (CMC), hydroxyethyl cellulose (HEC), polyacrylonitrile (PAN), and polyacrylamide (PAA) were used. All of them exert both pseudoplastic and viscoelastic viscosity behavior. Already at an early stage of these investigations, Opara [11] stated that it was not to be expected that a correlation between $n\theta$ and

Figure 8. Dimensions and installation conditions of stirrer types for vessel with $H/D = 1$ (Baffles drawn with dotted lines indicate that the stirrer can be used in baffled or unbaffled vessels.)

$Re_{\text{eff}} \equiv n\ d^2 \varrho / \mu_{\text{eff}}$ could be realized, because μ_{eff} is determined from the shear rates $\dot{\gamma}$, which occur at the largest rate differences, whereas the regions close to the walls, in which the smallest rate differences are to be found, are decisive for homogenization times. It is therefore not surprising that in all research studies the Weissenberg number $We \equiv N_1/\tau$ had to be included (N_1 is the first normal stress difference and τ is the shear stress) to achieve a satisfactory correlation; see [12–14]. For the dimensional-analytical treat-

Figure 9. Mixing-time characteristics of the stirrer types in Figure 8 [6]
Cross-beam stirrer a = 1.8 · c (i.e., the mixing time is 1.8 times that of Curve c); as = 1.8 · cs; grid stirrer b = 1.25 · c, bs = 1.25 · cs; blade stirrer c, cs; anchor stirrer d; helical ribbon stirrer e; MIG-stirrer f, fs; turbine stirrer gs; propeller stirrer hs; impeller stirrer i, is. In each case s indicates the presence of baffles.
Example: What value of θ is obtained when a liquid with $\nu = 10^{-4}$ m^2/s is mixed in a baffled vessel using a cross-beam stirrer (as = 1.8 · cs) with $d = 1$ m and $n = 1$ s^{-1} ?
$Re = nd^2/\nu = 10^4$
$n\,\theta = 1.26 \times 10$
$\theta \approx 13$ s

ment of non-Newtonian liquids → Scale-Up in Chemical Engineering, Chap. 5.3. and [3].

2.3. Power Characteristic

2.3.1. Definition and Measurement Method

In addition to the stirrer (shaft) power P, the motor drive of a stirrer must also account for the power losses in the gearbox and the seals. In order to determine the mixing power P, the torque M_d, and the stirrer speed n of the must be known: $P = M_\mathrm{d}\omega$, with $\omega = 2\,\pi\,n$ as the angular velocity. The torque can be measured using, for example, a torsion shaft with strain gauges, electrically with eddy current torque transducers, or mechanically using a swiveling motor. The stirrer speed can be measured using mechanical, electrical (photocell), or optical (stroboscope) instruments.

2.3.2. Power Characteristics in Homogeneous Systems

The power required by a given stirrer type in a given vessel configuration depends on the speed of rotation n, the stirrer diameter d, the density ϱ, and the kinematic viscosity ν of the medium. In vessels without baffles, the liquid vortex, and therefore the acceleration due to gravity g, is immaterial, as long as no gas is entrained in the liquid. Thus, $P = f\,(n, d, \varrho, \nu)$ applies, and in accordance with dimensional analysis $Ne = f\,(Re)$. Here, $Ne \equiv P/(\varrho\, n^3\, d^{\,5})$ is the Newton or power number, and $Re \equiv n\, d^{\,2}/\nu$ the Reynolds number. The relationship $Ne = f\,(Re)$ is called the power characteristic of a stirrer.

The power characteristics of the stirrer types discussed in this section are presented in Figure 10. Three flow regimes can be identified:

1) In the *laminar regime* ($Re \leq 10$; for stirrers with very small wall clearances, such as the anchor or helical ribbon mixer, $Re \leq 100$), the effect of inertial forces (density) is suppressed by the viscous forces; therefore, baffles are unnecessary. In this regime, $Ne \propto Re^{-1}$, or $Ne\,Re =$ constant; the power is therefore given by

$$P = k_1 n^2 d^3 \mu \tag{5}$$

μ being the dynamic viscosity, and k_1 being the constant.

2) In the *turbulent flow regime*, the viscosity, and therefore the Reynolds number, ceases to have an effect. In this case Ne = constant applies, and the power is given by

$$P = k_2 n^3 d^5 \varrho \tag{6}$$

This regime begins at $Re \geq 10^2$ for baffled vessels and at $Re \geq 5 \times 10^4$ for vessels without baffles. In this regime baffles are fully effective and increase the required stirring power by up to a factor of twenty. For example, the power characteristics of the blade stirrer in a vessel with baffles (cs) and without (c) can be compared.

3) The *transition regime* arises only in vessels without baffles and for $Re \simeq 10 - 5 \times 10^4$; in this case, both viscosity and density have an effect. The relationship $Ne \propto Re^{-1/3}$ applies here.

The stirring power can be determined from Equations (5) and (6) using the constants k_1 and k_2 from Table 1. In general, the power can be calculated using Equation (7). The Reynolds number is determined first, and the corresponding value of Ne read from Figure 10; using this value, the power can now be evaluated by:

$$P = Ne\, n^3 d^5 \varrho \tag{7}$$

The power characteristic for vessels without baffles decreases monotonically over a wide range of flow conditions; this offers the possibility of determining the viscosity of a reaction mixture and therefore the conversion, or the degree of polymerization, as a function of time by measuring the mixing power.

If large differences in density or viscosity exist at the start of mixing, it is advisable to calculate the mixing power using the larger of the two values.

Of the extensive literature on stirring power, the basic works of W. Büche [15], J. H. Rushton and co-workers [16], as well as S. Nagata and co-workers [17] should be mentioned. Power characteristics for various designs of turbine and paddle stirrers are given in [18]. Many power characteristics can also be found in the literature on mixing time [6–9].

Table 1. The proportionality constants for Equations (5) and (6)

Stirrer type	Curve	k_1	k_2
		$Ne\,(Re = 1)$	$Ne\,(Re = 10^5)$
Cross-beam stirrer	a	110	0.4
	a s	110	3.2
Grid stirrer	b	110	0.5
	b s	110	5.5
Blade stirrer	c	110	0.5
	c s	110	9.8
Anchor stirrer	d	420	0.35
Helical ribbon stirrer	e	1000	0.35
MIG stirrer	f	100	0.22
	f s	100	0.65
Turbine stirrer	g s	70	5.0
Propeller stirrer	h s	40	0.35
Impeller stirrer	i	85	0.20
	i s	85	0.75

2.4. Optimization: Minimum Work of Mixing

The optimum stirrer type and stirring conditions for the homogenization of a liquid mixture are those that require the least work of mixing. These conditions can be found quickly with Figure 11, which shows the relationship between the modified power number $Ne\,Re^3\,(D/d) \equiv P\,D\,\varrho^2/\mu^3$ and the modified mixing number $n\theta\,Re^{-1}\,(D/d)^{-2} \equiv \theta\,\mu/D^2\varrho$. This representation is based on the information in Figures 9 and 10. The stirrer whose curve lies lowest in Figure 11 gives the desired mixing time with the least power. For the sake of clarity, Figure 11 includes only the curves for the optimum stirrers along with their corresponding Reynolds number scales.

The use of the figure is as follows: first the modified mixing number is determined, and then the best stirrer type can be read off the abscissa. The abbreviations are explained in Table 1. The point of intersection of this value with the curve provides the stirrer speed via the Reynolds number, $Re \equiv nd^2\varrho/\mu$. The ordinate of this point gives the modified power number, and through this the mixing power. A specific example is worked out in Figure 11.

To obtain a value of the mixing number lower than $\theta\,\mu/D^2\varrho \simeq 10^{-4}$ is practically impossible. For liquids with viscosity similar to that of water and for large vessels, the following approximation is valid:

Figure 10. Power characteristics of the stirrer types in Figure 8 [6] (except g [18] and h [16])

Figure 11. Curves for determining the optimum stirrer type and the operating conditions that minimize the mixing work [6]
The numbers along the curves are the Reynolds number, $Re = nd^2\ \varrho/\mu$
Example: $D = 1.0$ m, $\mu = 1$ kg m s^{-1} = 1000 mPa · s, $\varrho = 1000$ kg/m^3, $\theta = 60$ s. $\frac{\theta\mu}{D^2\varrho} = 6 \times 10^{-2}$
Blade stirrer, without baffles (Fig. 8 C)
$D/d = 2$; $d = 0.5$ m
$Re = 170$; $n \approx 41$ min^{-1}
$PD\ \varrho^2/\mu^3 = 3 \times 10^7$; $P = 30$ W
The dotted arrows show this example in the figure itself

$$\theta_{\min} \simeq 10^{-4} D^2 \varrho/\mu$$

Following a suggestion in [19], the pairs of values ($n\theta$, Re) can be selected from Figure 9 in which both $n\theta$ and Re are lowest; using the corresponding Ne values from Figure 10, the following relationship can be derived from Figure 11:

$$\frac{P D \varrho^2}{\mu^3} = a \left(\frac{\theta \mu}{D^2 \varrho} \right)^{-3} \text{ or } \frac{P \theta^3}{\varrho D^5} \triangleq \frac{P \theta^3}{V \varrho D^2} = \text{constant} \quad (8)$$

where $a \simeq 700$. Two observations may be drawn from this relationship, which is valid in the turbulent regime (μ irrelevant):

1) at constant P/V, θ increases as $D^{2/3}$
2) at constant D, θ decreases as $(P/V)^{-1/3}$

This confirms that the constancy of P/V in the turbulent regime does not constitute a scale-up criterion for the homogenization of liquid mixtures.

If the corresponding values for the helical ribbon mixer in the laminar regime are inserted in the same relationship [19], then

$$\frac{P \theta^2}{D^3 \mu} = 5.8 \times 10^5 \quad (9)$$

This indicates that the constancy of P/V is a scale-up criterion only in the laminar regime. It also shows that: $\theta \propto (P/V)^{-1/2}$.

2.5. Homogenization in Storage Tanks

Stirrers are rarely used for homogenization in storage tanks since the liquids involved are of low viscosity and relatively long mixing times are generally acceptable. In such cases, mixing is carried out with side-entering propeller stirrers, liquid jets, or rising gas bubbles.

In homogenization using *propeller stirrers* [20], [21], one or more are introduced laterally through the wall of the tank at an angle of 7 – 10° to the radius. At this angle, liquid circulation is intensive without significant rotation of the contents. Since the mixing time θ and the liquid throughput q' of the stirrer are related through $\theta \propto V/q'$ (V = liquid volume), the operating conditions are chosen to maximize the liquid throughput at a given power. This is achieved through large stirrer diameter and low stirrer speed (Section 2.6). At $H/D = 1$ and P = constant, the following is valid:

$$\theta \propto (D/d)^{2.3} \quad 10 < D/d < 30$$

At a given d, the mixing time is inversely proportional to the power, $\theta \propto P^{-1}$, and increases rapidly with density differences, $\theta \propto (\Delta\varrho/\varrho)^{0.9}$ [20].

Two conditions can generally arise during the mixing:

1) At high mixing intensities, homogenization mainly depends on convection and turbulent diffusion.
2) At lower mixing intensities, which is commonly the case, small density differences lead to the formation of layers, which are subsequently broken up through interfacial waves. This process is much slower and depends to a great extent on the tank geometry and physical properties of the system.

In the second case, the boundary between the two flow regimes is defined by the value of the critical Froude number, $Fr'_{\text{crit}} \equiv n^2\, d\varrho/g\, \Delta\varrho$ [22]:

$$\log Fr'_{\text{crit}} = 1.40 + 0.04\,(D/d) \quad (10)$$

At $Fr' \gg Fr'_{\text{crit}}$, $n\theta$ is independent of Fr', but depends strongly on D/d:

$$n\theta = 90\,(D/d)^{1.3} \quad (11)$$

On the other hand, at $Fr' \ll Fr'_{\text{crit}}$, the following applies:

$$n\theta = 90\,(D/d)^{1.3} \left(Fr'_{\text{crit}}/Fr'\right)^{1.5} \quad (12)$$

The most favorable installation geometry for the propeller stirrer (also according to [23]) is $\alpha = +10°$ and $\beta = +10°$ (where α is the angle between the stirrer shaft and the horizontal, and b the angle between the shaft projected on the horizontal plane and the radius). The power characteristic of side-entering propeller stirrers is approximately 1/3 lower than that of a vertical stirrer [23].

In the homogenization with *liquid jets*, the mixing time can be estimated relatively accurately under the assumption $\theta \propto V/q'$ [21]. The total liquid throughput q' consists of the jet

stream itself and the entrained liquid. For calculation of the jet stream, see [24], [25]; for the estimation of liquid entrainment, see [26].

The liquids with relatively low viscosity ($n < 100\,\mathrm{mPa} \cdot \mathrm{s}$) can be homogenized effectively with *rising gas bubbles* from a distributor at the bottom of the tank (sintered or perforated plate, two-fluid nozzle). Their effectiveness is due to their buoyancy, and therefore mixing ability, remaining constant over the entire height of the tank. For liquids similar to water and without significant density or viscosity differences, the following relationship applies [27]:

$$\theta\,(g/D)^{1/2} = 4.75\,Fr^{-1/4}\left(dH^2/D^3\right)^{1/4} \tag{13}$$

where $Fr \equiv q^2/(D^5/g)$. After transformation, this becomes

$$\theta/D = 4.75\,(H/q)^{1/2}\,(d/g)^{1/4} \tag{14}$$

q is the gas flowrate, and d the diameter of the gas distributor. For the estimation of the gas flowrate for lower surface tensions or higher viscosities than that of water, refer to [27].

Homogenization with rising gas bubbles is also effective for the mixing of water reservoirs or lakes. Model measurements [28] yield the following relationship for the mixing time θ,

$$\theta = 250\left[H^4/(qg)\right]^{1/3} \tag{15}$$

which can be expressed in dimensionless form as

$$\theta\,(g/D)^{1/2} = 250\,Fr^{-1/6}\,(H/D)^{4/3} \tag{16}$$

2.6. Liquid Throughput of Stirrers

The liquid flowrate that is displaced through the area swept by the stirrer is termed the liquid throughput of the stirrer or its pumping capacity q'. This area is given by $\pi\,d^2/4$ for axially operating stirrers, and by $\pi\,db$ for radial flow stirrers, where b is the paddle height. For axial flow stirrers, q' is determined from the circulation time of particles with $\Delta\varrho \simeq 0$; for radial flow stirrers, it is obtained from the integral value of the measured velocity distribution of the flow.

In continuously stirred tanks, homogenization can only be achieved if $q' \gg q$, where q is the liquid flowrate through the vessel. Under these conditions, the mixing time is $\theta \propto V/q'$, where V is the liquid volume. In the case of propeller stirrers, knowledge of q' enables calculation of the flow velocity along one or more spiral coils concentric to the stirrer. The installation of such coils may be unavoidable in the case of extremely exothermic reactions.

The throughput characteristic of a given stirrer is provided by $Q' = \mathrm{f}(Re, D/d, h/d)$, where $Q' \equiv q'/(nd^3)$ represents the dimensionless throughput number; $Re \equiv nd^2/\nu$ the Reynolds number; and D/d, h/d the geometric parameters of the stirrer installation. For propeller stirrers with pitch $s = 1$ (pitch s = tangent of the blade angle α) operating in baffled vessels with $H/D = 1$, the following relationship is valid in the turbulent regime ($Re > 10^3$) [35]:

$$Q' = 0.654\,(D/d)^{-0.16} \quad D/d > 3 \tag{17}$$

For paddle stirrers with six pitched paddles ($\alpha = 45°$, $b/d = 0.2$), the relationship is as follows [36]:

$$Q' = 1.29\,(D/d)^{-0.20}\,;\; 2 < D/d < 3.3 \tag{18}$$

For turbine stirrers with six paddles, as in Figure 8 G, the throughput is given by [37]:

$$Q' \simeq 0.75 \tag{19}$$

Other stirrer configurations and paddle numbers are treated in [38].

2.7. Vortex Depth in Unbaffled Stirred Tanks

All calculations for the design of stirrers in unbaffled vessels are valid only under the assumption that the vortex does not reach the stirrer head, otherwise, gas entrainment alters the physical properties of the system. The highest allowable rotation speed is given by the following relationships [39].

Propeller stirrer with $D/d = 3.33$ and $h/d = 1$ (Fig. 8 H):

$$Fr_{\max} = 0.072\left(H'/d\right)^{1.33}/\left(0.25 - Ga^{-0.10}\right) \tag{20}$$

Turbine stirrer with $D/d = 3.33$ and $h/d = 1$ (Fig. 8 G):

$$Fr_{\max} = 0.016\,(H'/d)^{1.16} / (0.10 - Ga^{-0.18}) \quad (21)$$

These expressions are valid over the range $2.3 < H'/d < 5.7$ and $10^6 < Ga < 10^{10}$. In these equations, $Fr_{\max} \equiv n^2_{\max}\, d/g$ is the Froude number; H' the height of liquid above the stirrer; and $Ga \equiv d^3 g/\nu^2$ the Galileo number. For other stirrer types and geometries, see [39–41].

3. Intensification of Heat Transfer

3.1. Problem Definition

Stirrers are often used to intensify the heat transfer between the liquid and the heat exchange surface in a vessel. The question is what type of stirrer to use and under what conditions so that the desired heat flux can be effected at a minimum expense (inexpensive stirrer, low power requirements). In the case of cooling, this question involves an optimization problem: high stirrer speeds result not only in an increase of the heat flux, but also in a higher heat of agitation.

3.2. Heat-Transfer Characteristics

3.2.1. Definitions

Heat transfer is described through the general heat-transfer equation $Q = UA\,\Delta T$, where Q is the heat flowrate, A the heat-exchange surface area, and ΔT the temperature difference. The overall heat-transfer coefficient U is composed of inner and outer film heat-transfer coefficients, h_i and h_o, the thermal conductivity of the wall material, k, and of the wall thickness, δ, according to the relationship

$$1/U = 1/h_o + \delta/\lambda + 1/h_i$$

Stirring affects only the inner-side heat-transfer coefficient h_i. This coefficient is defined through the relationship $h_\mathrm{i} \equiv Q/(A\,\Delta T)$, where the characteristic temperature difference ΔT is generally taken to be the difference between the average wall temperature T_w and the average temperature of the the bulk liquid T, i.e., $\Delta T = —T_\mathrm{w} - T—$.

For a given stirrer type and a fixed geometry, h_i is a function of the vessel diameter D, the stirrer diameter d, and the stirrer speed n, as well as the physical properties of the liquid (specific heat capacity c_p, heat conductivity k, density ϱ, dynamic viscosity in the bulk μ and at the wall μ_w): $\alpha_\mathrm{i} = \mathrm{f}\,(D, d, n, c_\mathrm{p}, \lambda, \varrho, \mu, \mu_\mathrm{w})$. Dimensional analysis (→ Scale-Up in Chemical Engineering) yields the following expression:

$$Nu = f\,(Re, Pr, Vis, D/d) \quad (22)$$

where $Nu \equiv h_\mathrm{i}\,D/\lambda$ is the Nusselt number, $Re \equiv nd^2\,\varrho/\mu$ the Reynolds number, $Pr \equiv c_\mathrm{p}\mu/\lambda$ the Prandtl number, $Vis \equiv \mu_\mathrm{w}/\mu$, and D/d the diameter ratio. The relationship between these dimensionless numbers is termed the heat transfer characteristic.

3.2.2. Heat-Transfer Characteristics in the Range Re > 200

In this flow regime, heat-transfer characteristics are generally of the form $Nu = \mathrm{c}\,Re^{2/3}\,Pr^{1/3}\,(\mu/\mu_\mathrm{w})^\mathrm{m}$, where the constant c is a function of the stirrer type and the nature of the heat exchange surface (baffled or unbaffled tank wall, spiral or meander coil). The exponent of the viscosity term, m, which enables both heating and cooling data to be presented together, has been found to be 0.14, 0.18, or 0.24 in several investigations. Studies, which separately investigated the effect of viscosity, revealed that the exponent m of Vis is not a constant, but a function of the sort: $m = -\,aVis^{-b}$. For details see [1], Section 7.4.

Table 2 lists the values of the constant c for various stirrer types for heat transfer through the tank wall (W) or a spiral coil (S); these values are taken from [42], in which 77 original works are evaluated and compared. A further collection of such expressions is given in [43].

The constant of the heat-transfer characteristic c has the following values:

1) Unbaffled vessels, $c = 0.35 - 0.4$, independent of stirrer type and diameter ratio
2) Baffled vessels, $c = 0.5$ for axial flow mixers (e.g., propeller stirrers) and $c = 0.75 - 0.80$ for radial ones (e.g., blade and turbine stirrers)
3) Tanks with spiral coils, $c = 0.70 - 0.90$ for radial flow stirrers, independent of whether baffles are present or not, whether inside or outside the coil.

Table 2. Values of c in the relationship $\mathrm{Nu} = c\,\mathrm{Pr}^{1/3}\,\mathrm{Re}^{2/3}\,(\mu/\mu_w)^{0.14}$

Stirrer Type and Installation	*c*	*Re* Range	Reference [d]
Cross-beam stirrer with one beam, $D/d = 1.67$, $\delta/D = 0.16$, no baffles, spiral coil	W 0.36 S 0.78 [a]	$3\times10^2 - 3\times10^5$	[44]
Two paddle stirrers with 6 paddles, arranged one above the other, $D/d = 2.5$, $\delta/d = 0.16$, no baffles, spiral coil	W 0.40 S 0.70 [a]	$2\times10^2 - 1\times10^6$	[39]
Blade stirrer $D/d = 2.0$, $b/d = 1.42$, no baffles, spiral coil	W 0.36 S 0.70 [a]	$1\times10^3 - 1\times10^6$	[45]
Blade stirrer, 4 baffles (D/15 wide), $D/d = 2.0$, $b/d = 1$, $d/D = 0.25 - 0.60$, $b/D = 0.10 - 0.60$	W 0.80 W 1.31 $(d/D)^{0.39}(b/D)^{0.34}$	$3\times10^2 - 5\times10^5$	[46]

3.2.3. Heat-Transfer Characteristics in the Range Re < 200

In the laminar flow range $Re < 10^2$ heat conduction dominates and the effect of density and viscosity disappears entirely, like in solid bodies. To account for this physical situation, Reynolds and Prandtl numbers have to be combined such as to eliminate ϱ and μ;. Then the heat transfer characteristic is given as:

$$Nu = \text{const}\, Pe^a Vis^{-b}\,(d/D)^c$$

where the Peclet number $Pe \equiv PePr = nd^2\varrho c_p/k$ (Note: ϱc_p denotes the heat capacity per unit volume!).

Ishibashi et al. [51] investigated the heat transfer behavior in a vessel with a single or double helix ribbon stirrer (with an inner and outer helix) and found that:

$$Nu = 2.0 Pe^{1/3} Vis^{-0.14} \qquad Re = 5 - 50$$

$$Nu = 1.0 Re^{1/2} Pr^{1/3} Vis^{-0.14} \quad Re = 50 - 500$$

and for a centrally mounted screw stirrer [51]:

$$Nu = 1.0 Re^{1/2} Pr^{1/3} Vis^{-0.14} \quad Re = 5 - 50$$

KURIYAMA et al. [52] proposed the following relationship for the double helix ribbon stirrer for cooling and heating and for different pitches (p) and clearances $c = (D - d)/D$:

$$Nu = 0.64 Pe^{1/3} (D/d)^{2/3} (p/c)^{1/3} Vis^{-0.14}$$

The experimental data of ZLOKARNIK [53] with an anchor stirrer with $d/D = 0.98$ can also be interpreted in the range $Re = 0.5 - 100$ as $Nu \propto Pe^{1/3}$. However, the following relationship was selected instead, which satisfactorily covers the whole Re range:

$$Nu = \text{const} \left(RePr^{1/2} + 4 \times 10^3 \right)^{2/3} Vis^b$$

The comparison between the anchor stirrer and a double helix ribbon stirrer with a pitch of 0.5 for the same $d/D = 0.98$ established that the helical ribbon stirrer for $Re \approx 1$ provided a Nu value which was approximately double that with the anchor stirrer. However, this superiority had already been lost at $Re \approx 100$ [53]. Apparently, here the radial flow component is entirely sufficient for heat transfer.

If considerable intensification of heat transfer is required for $Re < 100$, a stirrer with a very small wall clearance ($d/D \rightarrow 1.00$) is recommended. ZLOKARNIK found no effect of clearance in the whole Re range for anchor stirrers with $d/D = 0.91 - 0.98$, but an extremely large increase in heat flow for $d/D \approx 1.0$ (without wiper blades!) [53]. For cooling, the heat flow is approximately a factor of 4 higher, whereas for heating an increase of only about a factor of 2 was found. These results can be described by the relationship

$$Nu = a \left(RePr^{1/2} + b \right)^{2/3} Vis^c$$

For the range $Re = 10 - 200$, UHL and VOSNICK found the dependence [54]

$$Nu \propto Re^{0.5} Pr^{1/3}$$

whereas PENNEY and BELL confirmed the expected relationship (for $Re < 100$) [55]

$$Nu \propto Pe^{1/3}$$

Removal of the boundary layer from the inside wall of the tank to a considerable extent is only possible with stirrers with wiper blades. (For the numerical analysis of the three-dimensional flow and thermal behavior in a scraped-surface heat exchanger see [56].) A first review over such stirrers in [55] brought little of substance. NAGATA provided the following relationship for helical ribbon stirrers with wipers [57]:

$$Nu = 6 Pe^{1/3} Vis^{-0.20}$$

JSUDAT investigated the heat exchange behavior in a stirred tank ($D = 444$ mm, $H = 1080$ mm; $H/D = 2.43$) with helical ribbon stirrers ($d = 340$ mm; pitch 1), on which one, two or four wiper pairs (number of wipers $i = 2; 4; 8$) were so mounted on the shafts, that they pressed firmly on the inside wall of the tank upon rotation, as a result of hydraulic forces [58].

Figure 12 shows the evaluation of these measurements for $i = 4$. As can be seen, the correlation gives satisfactory results in the laminar range ($Re < 10^2$) and in the turbulent range ($Re > 10^4$):

$$Re < 10^2 : Nu = 10 Pe^{1/3}$$

$$Re > 10^4 : Nu = 0.5 Re^{2/3} Pr^{1/3}$$

In the creeping flow range of $Re < 10$, the insertion of wiper blades improves the heat transfer by a factor of 10!

In the transition range, spreading of measuring data with the stirrer speed appears, and indeed the more strongly, the higher the rotation speed. This phenomenon is satifactorily explained by the modified penetration theory of RAUTENBACH and BOLLENRATH [59].

3.3. Stirrer Power During Heat Transfer

The relationships in Section 2.3. also apply to the stirrer power in heat transfer. If wall clearances are small, the viscosity at the wall temperature should be used to calculate the Reynolds number.

Figure 12. Heat transfer characteristic of a helical ribbon stirrer with hydraulic pressing wiper blades (2 wiper pairs, $i = 4$); according to [58]

3.4. Optimum Stirring Conditions for the Removal of Reaction Heat

Heat removal is a particularly severe problem in the case of strongly exothermic reactions in viscous mixtures. Figure 13 illustrates the problem with an example. The values of the rate of heat transfer Q through the wall, as well as the stirrer power P, are plotted as functions of the speed of rotation n. These values are calculated using the heat-transfer and power characteristics of the anchor stirrer (Fig. 10 and [53]). In the appropriate range of Reynolds numbers ($5 \leq Re \leq 50$), stirrer power increases much more rapidly with the stirrer speed ($P \propto n^2$) than the heat flux ($Q \propto h \propto n^{1/2}$). The thick curve represents the difference between the two straight lines on the log-log plot and corresponds to the heat of reaction $R = Q - P$ that can be removed through the wall: R goes through a maximum at $n \simeq 20\,\text{min}^{-1}$ and reaches zero at $n = 59\,\text{min}^{-1}$. At this point, the heat removed is that generated by the stirrer itself.

Figure 13. Graphical representation of the relationship between Q, P, $R = Q - P$, and the rotational speed n [60] Anchor stirrer in a vessel with $D = 2.0\,\text{m}$, $V = 5.86\,\text{m}^3$, $d = 1.8\,\text{m}$ ($D/d \simeq 1.10$), $\varrho = 1000\,\text{kg/m}^3$, $\mu = 50\,\text{kg/(m} \cdot \text{s)}$, $k = 2\,\text{W/(m} \cdot \text{K)}$, $c_p = 2000\,\text{J/(kg} \cdot \text{K)}$, $A = 14\,\text{m}^2$, $\Delta T = 25°\text{C}$, $h \approx U$

PCs and pocket calculators of today are useful tools for a quick determination of the optimum stirring conditions. The only thing to do is to insert the respective process equations for

$Ne(Re)$ and for $Nu(Re, Pr)$, then the dependence $R = Q - P = f(n)$ can be calculated. Thirty years ago, when these devices were not available, a nomogram was developed to facilitate this calculation [60].

The determination of the optimum stirring conditions has also been treated by PENNEY and KOOPMAN [61]. They found that in the laminar regime the maximum amount of reaction heat can be removed when the stirrer power is approximately 20 % of the heat of reaction; in the turbulent regime, this figure is 5 – 20 %.

4. Suspension of Solids in Liquids (S/L Systems)

4.1. Problem Definition

Suspension is connected with the presence of a dispersed solid phase, which is suspended ("whirled up") in the liquid. The material system solid – liquid (S/L) is thus involved. Occasionally a gas is distributed and dispersed in the liquid at the same time, in this case the material system concerned is a solid – liquid – gas (S/L/G) system.

For solids to be dissolved rapidly in liquids, their total surface must be accessible to the liquid, i.e., the solid particles must be completely suspended. In this case that critical stirrer speed n_{cr} is of primary interest, at which this state is just attained, and the other stirring conditions (stirrer type and installation), which ensure the maintenance of these flow conditions with the lowest stirrer power.

In crystallization or in solid catalyzed chemical reactions it is, on the other hand, generally necessary, that the dispersed phase is largely uniformly distributed over the whole liquid height. This condition naturally requires both a higher stirrer speed and power and occasionally also another stirrer type than suspension alone.

4.2. Classification of the Suspension Conditions

Two suspension criteria have become established, namely complete suspension and homogeneous suspension. A *complete suspension* is achieved, when no particle or no particle cluster remain on the bottom for more than 1 s This so-called 1-s criterion establishes the critical stirrer speed n_{cr} and is due to ZWEITERING (1958) [102]. This time criterion is easy to determine, but represents an inaccurate measured quantity with a low sensitivity.

The term *homogeneous suspension* describes a state in which the solid particles are homogeneously distributed over the whole liquid height. It concerns a suspension state, which is particularly aspired to, if the suspension must be continuously conveyed through the vessel. Since this state is difficult to achieve and to measure, in 1977 EINENKEL suggested that a "homogeneous suspension" should be referred to when the height of the suspended particle layer, h_p, attains 90 % of the liquid height [62]. Above this a usually clear, particle-free liquid layer is produced. The height h_p of the suspension zone can be measured with ± 5 % accuracy, particularly for small particles. The particle layer height criterion of $h* = 0.9$ is introduced, whereby $h* \equiv h_p/H$ represents the relative height, i.e., the particle layer height h_p related to the total liquid height H, n_{cr} coincides with the discontinuity in the $h*(n, \varphi_v)$ dependence, because for $n < n_{cr}$ the stirrer power also has to suspend an increasing number of particles from the bottom, whereas the additional power above $n = n_{cr}$ is utilized for increasing the particle layer height [62].

For the distribution of solids upon suspension see [103].

4.3. Suspension Characteristic

When different criteria for describing the suspension state are in use, these must also be taken into consideration in the formulation of the suspension characteristics. Depending on which criterion is used in the determination of the critical stirrer speed n_x, where the subscript x denotes the 1-s criterion or the particle layer height criterion $h* = 0.9$, the process numbers are correspondingly designated.

Initially, the average particle size d_p was taken as the characteristic length of the solid particle and the geometrical number d_p/d was thus formed. It was evident, however, that the

pi-spaces, which in addition to $g\Delta\varrho$ only considered this geometrical number, differentiated too strongly and led to contradictory scale-up rules.

On the basis of the analogy between $n_{0.9}$ and d_p, on the one hand, and the sinking velocity of the particle swarm w_{ss} and d_p, on the other, w_{ss} was later incorporated into the relevance list, because this leads to a better physical interpretation of the process.

4.3.1. Suspension Characteristics with d_p as the Characteristic Particle Dimension

This suspension characteristic is as follows:

$$\{Re_x, Fr'_x, d_p/d, \varphi_m\} \text{ or } \{Re_x, Ar, d_p/d, \varphi_m\}$$

where

$Re_x \equiv \frac{n_x d^2}{\nu}$	is the critical Reynolds number as target number,
$Fr'_x \equiv \frac{n_x^2 d \varrho}{g\Delta\varrho}$	is the Froude number extended by $\varrho/\Delta\varrho$, which is usually converted into
$Ar \equiv \frac{Re^2}{Fr'} \equiv \frac{d^3}{\nu^2}\frac{g\Delta\varrho}{\varrho}$	which is the Archimedes number and φ_m is the mass portion of solids in the liquid.

In a comprehensive study Kneule and Weinspach [63] have derived the suspension characteristics for the 1-s criterion with a number of stirrer types in baffled and unbaffled vessels with differently shaped bottoms (dished, hemispherical, truncated cone, flat) by using two tank sizes ($D = 0.37$ and 2.07 m) and different solid particles $\varrho_s = 2.630$ to 11.100 kg/m^3; $d_p = 1.1 - 10$ mm with mass fractions $\varphi_m = 0.02$ to 0.25. These characteristics can be divided into two parts. The turbulent Reynolds range begins at $Re_{1s} > 130\ (d/d_p)$ in which the liquid viscosity and therefore Re_{1s} is irrelevant and the process characteristic is hence given by

$$Fr'_{1s} = \text{const}_1\ \varphi_m^{0.5} \tag{23}$$

The corresponding numerical values in Equation (23) for propeller stirrers, which convey downwards, and turbine stirrers are 3.06 and 1.21, respectively. Therefore, in the same material system, the propeller stirrer must operate with a factor of $(3.06/1.21)^{0.5} = 1.59$ higher stirrer speed than an identically sized turbine stirrer to maintain the solids in suspension.

On the other hand, according to [63], for tests in the transition range $Re_{1s}\ (d/d_p) = 13 - 130$, the following applies:

$$Re_{1s} = \text{const}_2\ Ar^{0.4}\ [(d/d_p)\ \varphi_m]^{0.2} \text{ or}$$
$$Fr'_{1s} = \text{const}_2\ Re^{-0.5}\ [(d/d_p)\ \varphi_m]^{0.5} \tag{24}$$

The numerical values of const_1 and const_2 in the two process relationships (23) and (24) are summarized in tables for a number of stirrer types and the above-mentioned geometric ratios [63]. It emerges that the dished bottom is insignificantly less favorable than the hemispherical bottom for suspending solids. The shape of the bottom must be in such a condition that it conveys the solids to the center, where the stirring effect is the strongest. The D/d ratio exerts a very strong effect; D/d of ca. 3.3 is regarded as optimal. In the range $0.3 < h/d < 0.8$, the h/d ratio has practically no effect, a h/d ratio of ≈ 0.5 being recommended. As stirrer type, propeller stirrers, which convey axially downwards, are recommended as well as radially acting double turbines.

Lamadé [64] has evaluated the suspension characteristics for three different enameled stirrers (Pfaudler impeller, pitched-blade, paddle stirrers) in the turbulent flow range and found a process relationship of the form:

$$Fr'_{1s} \propto (d_p/d)^{0.42}\ \varphi_m^{0.3}\ (h/d)^{0.23(d/D)^{1.5}} \tag{25}$$

Fr'_{1s} increases with h/d to the power of $(d/D)^{1.5}$!

Einenkel [65] compared eight earlier studies dealing with the suspension of solid particles with propeller stirrer in the turbulent range and found for the process relationship of the type:

$$Re_{1s} \propto Ar^a\ (d_p/d)^b\ \varphi_m^c$$

the following exponents: $a = 0.45$ to 0.6; $b = -0.2$ to $+0.25$; $c = 0.25$ to 0.28.

There are still several studies to be mentioned, in which the experimental data was evaluated in the same way:

- twelve-turbine stirrer with paddles covered on both sides, different particles (sand, glass, siderite with $d_p = 0.1 - 1.25$ mm), kinematic viscosity of the liquid $\nu \times 10^6 = 1 - 160$ m^2/s [66]:

$$Fr_{1s} = 1.07 \times 10^{11}\ Re^{-2}\ \varphi_m\ (d/d_p)^{2.5}\ \ 10^{-2} < Ar < 10^6$$

- four- and six-pitched-blade stirrers in tanks with flat bottoms [67]:

$$Re_{1s} = a\,Ar^{0.5}\,\varphi^{0.25} \text{ applies for}$$
$$Ar\,(d_p/d)^2\,\varphi^{0.5} = 2 \times 10^3 - 3 \times 10^4$$

- six-pitched-blade stirrers, $D/d = 3$; $h/d = 0.5$; flat bottom [68]:

$$d_p/D < 7 \times 10^{-3}\text{: } Fr'_{1s} = 16.6\,(d_p/D)^{0.6}$$

$$d_p/D > 7 \times 10^{-3}\text{: } \mathrm{Fr}'_{1s} = 0.86$$

These relationships apply for $\varphi_v = 0.025$ and $d_p/D = 2 \times 10^{-4} - 3 \times 10^{-2}$.

- six-turbine stirrer at different installation conditions [69]:

$$Fr_{1s} = 0.61\,(d_p/d)^{0.38}\,(h/d)^{0.35}\,(D/d)^{2.5}\,\varphi^{0.32}$$

- six-blade and pitched-blade turbine at extremely low bottom clearances ($h/d = 0.021 - 0.25$) and different liquid viscosities [70].

4.3.2. Suspension Characteristics with w_{ss} as the Characteristic Particle Property

The sinking velocity of the swarm, w_{ss}, cannot be measured, but it can be calculated from the sinking velocity w_s of a single particle according to different expressions of the type:

$$w_{ss} = w_s\,f\,(\varphi_v),$$

where φ_v is the volume fraction of the solids in the liquid [1].

Because w_{ss}/w_s does not depend upon d_p/d, it cannot replace this parameter in the pi set. Whether w_{ss}/w_s can completely replace φ_v, can only be determined experimentally. The suspension characteristics with w_{ss} as the characteristic particle property therefore reads:

$$\{Re_x, Fr_x, w_{ss}/w_s, d_p/d, \varphi_v\} \text{ or}$$
$$\{Fr_x, Ar, w_{ss}/w_s; d_p/d, \varphi_v\}$$

There are many experimental studies which evaluated the results in this way, see [1]. In the following only the results of KRAUME and ZEHNER [71] and of EINENKEL [73] will be presented. In both cases, the quotient $P_{0.9}/P_{sink}$ was taken as the target quantity. $P_{0.9}$ is the stirring power needed to achieve $h* = 0.9$ and P_{sink} is the power consumption of the sinking particle swarm, which corresponds to the minimum stirring power to keep the particles in suspension. KRAUME and ZEHNER evaluated their experimental data in the pi space [71]

$$\{P_{0.9}/P_{sink},\, D^*\} \quad \text{with} \quad D^* \equiv$$
$$(Ar\,\varphi_v\,Re_{ss}/C_f)^{1/3} \equiv \frac{D}{\nu}\left(\frac{g\Delta\varrho}{\varrho}\,\frac{\varphi_v\,w_{ss}\,D}{C_f}\right)^{1/3}$$

The measurements with turbine and propeller stirrers were carried out both in laminar ($D = 0.1$ m, viscous medium, low w_{ss}) and turbulent ($D = 1.0$ m, low viscosity medium, high w_{ss}) ranges. The target quantity was $n_{0.9}$for which the Reynolds number of the stirrer must also be $\mathrm{Re} > 10^3$. The results are presented in Figure 14. The fitted curve for the turbine stirrer is:

$$\frac{P_{0.9}}{P_{sink}}\,\frac{d}{D} = 7.5 + 1.08 \times 10^4\,D^{*-3/4}$$

and for the propeller stirrer

$$\frac{P_{0.9}}{P_{sink}}\,\frac{d}{D} = 2.5 + 3.6 \times 10^3\,D^{*-3/4}$$

Experimental data from BREUCKER (1986) [71] and the correlation due to EINENKEL [72] are also inserted into the bottom figure. It can be seen that the relationship found by EINENKEL ($P_{0.9}/P_{sink} \propto D^{*-1/3}$) can indeed be included into the total picture, but that it only applies in a small $D*$ range. He later simplified this rather complicated dimensionless frame, but his approach is valid only for $\varphi_v \to 0$ [73].

4.4. Power Requirements Upon Suspension of Solids

WEINSPACH [104] has determined the power characteristics for the downwards conveying propeller stirrer and for the on both sides partly covered double turbine in suspension operation. Here the density and the dynamic viscosity of the suspension were defined as follows:

$$\varrho_{sus} = \varrho + \varphi_v\,(\varrho_{susp} - \varrho)$$

Figure 14. Dependence of the power ratios for $n_{0.9}$ as a function of the dimensionless tank diameter $D*$ for turbine and propeller stirrers; from [71]

$$\mu_{\text{sus}} = \mu \left(1 + \frac{1.25\,\varphi_{\text{v}}}{(1 - \varphi_{\text{v}}/\varphi_{\text{v,max}})}\right)^2$$

where φ_{v} is the average volume fraction of solids in the suspension, $\varphi_{\text{v,max}}$ is the maximum fraction of solids in the closest spherical packing ($\varphi_{\text{v,max}} = 0.74$) and μ is the dynamic viscosity of the homogeneous liquid; μ was varied in this study by adding tylose (methyl cellulose with Newtonian viscosity behavior).

It was found that up to $\varphi_{\text{v}} = 0.25 - 0.30$ suspensions behave as homogeneous mixtures, i.e., up to these φ_{v} values no dependence of Ne_{sus} on φ_{v} was found. If Ne and Re numbers are formulated with the material properties valid for suspensions and are represented as $Ne_{\text{sus}}(Re_{\text{sus}})$, the curves for $Re > 5 \times 10^2$ and $\varphi_{\text{v}} < 0.25 - 0.30$ coincide within experimental accuracy.

The stirrer which operates most favorably energetically is the one which requires the lowest stirrer power at the critical stirrer speed. In the turbulent flow range, for which $Fr' = \text{const}$ applies (see. Eq. 23), this condition is described by the relationship $NeFr'^{3/2} = \text{min}$. With $Ne = 0.35$ and 5.0 (see Table 1) for the propeller and turbine stirrers, respectively, and the above-mentioned constants for Equation (23) it can be calculated that the propeller stirrer only requires 28 % of the power of the turbine stirrer. From an energetic point of view stirrer types which convey the liquid axially downwards are clearly superior to axially operating ones.

4.5. Scale-up of the Solids Suspension Process

Studies in the 1980s and 1990s yielded different scale-up rules [1]. It should be recognized that always discrepancies occur between the individual studies. It can, however, be taken as proven, that two flow ranges exist, whereby in the turbulent range ($D \geq 1.0$ m, low viscosity medium, high w_{ss}) the scale-up rule P/V = idem can be seen as reliable.

4.6. Effect of Geometric and Apparatus-Related Factors on the Suspension

In this context four aspects are worth mentioning:

1) HERNDL [74] investigated the influence of the d/D ratio on the critical stirrer speed for suspension and found that it decreased approximately with the inverse of the square of the stirrer diameter:

$$n_{cr} \propto d^{-1.88}$$

This result shows that from an energetic standpoint it is most favorable to operate with a larger stirrer and correspondingly smaller stirrer speed, since the above expression corresponds to

$$P \propto d^{-0.64}$$

2) CHUDACEK [75], [76] investigated the influence of different bottom shapes on the suspension process. He used tanks with flat bottoms, with a completely profiled bottom (a) and a bottom provided with a cone in the middle and a sloping rim along the walls (b). As regards the dependence $P/V = f\ (h*)$, construction (a) always proved to be the best, if materials which are easily suspended are being dealt with. Bottom profile (b) is almost equally suitable to (a) in the case of rapidly sedimenting particles, otherwise it is intermediate in suitability between the profiled and flat bottoms. Only if slurry above the complete suspension has to be maintained in suspension, is (a) slightly more suitable. In summary, design (b) represents a considerable improvement over a flat bottom and is considerably simpler and cheaper than the fully profiled bottom (a).
3) BUURMAN et al. [77] have established through measurements (1-s criterion) in two differently sized tanks, equipped with a four-pitched blade stirrer ($a = 45°$, $d/D = 0.4$), that in the flow range investigated by them the scale-up rule P/V = const applies and that thin stirrer paddles are advantageous for saving power, because they produce eddies in the lower range of the turbulence spectrum, which is determining for suspension process. This corresponds to the Kolmogorov microscale $\lambda \approx 40\ \mu$m. BUURMAN et al. found:

$$Fr'\ (d/d_p)^{1/3} = \text{const.}\ (b/d)^{1/2}$$

where b is the paddle thickness.
Since for strength reasons b cannot be reduced without any limit, it is suggested that the paddle edges be slanted (for details see [1]). Measurements showed, that in this way the stirrer speed could be reduced by 5% and the stirrer power reduced by 17 %.
4) Turbine stirrers with larger paddle surfaces than the standardized (Rushton) turbine stirrer, but each provided with six perforations, which are sufficiently large so that they have an identical active paddle surface, exhibit a significantly lower power characteristic than standard turbine stirrer [78].

4.7. Mass Transfer in the Solid – Liquid (S/L) System

The enhancement of mass transfer in the solid – liquid system is a frequent stirring operation. Very often salts must be dissolved in the liquid, to prepare a salt solution or to initiate a chemical reaction. To accelerate the dissolution process, the whole surface of the solid particles must be wetted as completely as possible by the liquid and the liquid flow should be turbulent, so that the boundary layer on the liquid side is small and the transfer of the dissolved material to the bulk of the liquid proceeds rapidly.

The thermodynamic reason for the mass transfer in the solid – liquid system is the leveling out of the chemical potentials μ between the two phases. In the solid – liquid system, the change from $\Delta\mu$ to Δc is simpler to comprehend than in the G/L system, because the equilibrium concentration in the phase boundary S/L is given here by the saturation concentration $c* = c_s$, which immediately adjusts to the thermodynamic equilibrium in the phase boundary.

In comparison with mass transfer in gas-liquid (G/L) systems solid-liquid systems have two advantages: (a) the exchange surface is independent of the stirring intensity; (b) the saturation concentration c_s is only a function of temperature and the physical properties of the liquid phase.

The process characteristic of mass transfer in the S/L system reads

$$\{Sh, Ar, Sc, Re, d_p/d)\}$$

where

$Sh \equiv k_L d_p/D$	is the Sherwood number
$Ar \equiv d_p^3\, g\Delta\varrho/\varrho\, \nu^2$	is the Archimedes number
$Sc \equiv \nu/D$	is the Schmidt number
$Re \equiv n\, d^2/\nu$	is the Reynolds number
d_p/d	is the geometric ratio

Figure 15. Dependence of the process characteristic of mass transfer in the S/L system upon the state of suspension; from [79]

As early as 1941 Hixon and Baum [79] pointed out that the process characteristic of this pi space depended essentially on the particular suspension condition concerned (see Fig. 15). Before the condition of complete suspension, the fraction of the particles, that are suspended and wetted by liquid, is particularly increased with increasing stirrer speed. Subsequently only the liquid boundary layer is further reduced. This is also expressed in the two process characteristics:

$$Re < Re_{cr}: Sh\, Sc^{-0.5} \propto Re^{1.44}$$

$$Re > Re_{cr}: Sh\, Sc^{-0.5} \propto Re^{0.58}$$

For the suspension conditions in the system S/L/G and the mass transfer involved see [1].

5. Dispersion in Liquid – Liquid (L/L) Systems

Dispersion in liquid – liquid (L/L) systems is associated with the enlargement of the interface area between two immiscible liquids, so that, e.g., an extraction process or a chemical reaction (saponification, nitration, etc.) can proceed rapidly or dispersions of particular droplet size are produced (bead and suspension polymerizations, etc.). In this chapter only dispersion by stirrers is considered. If this process is assisted by the addition of surface-active substances, it is termed emulsification, for which completely different laws generally apply.

In general the phase with the smaller volume is mixed into the other, continuous phase and broken up into droplets therein (dispersed phase). However, in the case of phases with comparable volume fractions, the possibility of inversion exists, which phase becoming the continuous one depends on the dispersion starting conditions (e.g., in which phase the stirrer is to be found) and on the physical properties of the system. For details see [1].

In dispersion in L/L systems the quantities of interest are the lowest stirrer speed at which one phase is completely mixed into the other, the achievable droplet size or droplet size distribution, the size of the interfacial area and the mass-transfer coefficient.

5.1. Lowest Stirrer Speed for Dispersion

In analogy with suspension in S/L systems, for which the lowest, critical stirrer speed at which

small particles are no longer to be found on the bottom is important, that stirrer speed at which a phase is completely stirred into the other is of interest in dispersion in L/L systems.

It is to be expected that this lowest stirrer speed $n_{\min}$ is dependent on the material system and the stirrer type. Many works treated this problem and produced similar process equations. These can be reduced to the relationship $n_{\min}\, d^{\mathrm{a}}$ = idem. Two statements are possible:

1) How does $n_{\min}$ behave upon scaling-up ($\mu \equiv d_{\mathrm{T}}/d_{\mathrm{M}}$ = scale factor)? Answer:

$$\frac{(n_{\min})_T}{(n_{\min})_{\mathrm{M}}} = \mathrm{const}\,\mu^a \qquad a = -2/3 \text{ to } -3/4$$

2) How does $(P/V)_{\min}$ behave upon scaling-up? Answer:

$$\frac{(P/\varrho V)_{\mathrm{T}}}{(P/\varrho V)_{\mathrm{M}}} = \mathrm{const}\,\mu^b\,;$$
$$b \equiv (2-3a) = -2.8 \text{ to } -3.1$$

It is evident, that both $n_{\min}$ and also the associated stirrer power per unit volume become smaller upon scaling-up.

5.2. Dispersion Characteristics

During dispersion a steady-state situation is established, in which the droplets formed coalesce to ever larger droplets and are broken up anew by the stirrer. The droplet size distribution of the dispersion produced by stirring is usually characterized by an average droplet size d_{32}, which is defined by the expression:

$$d_{32} \equiv \frac{\sum (n_i\, d_i^3/6)}{\sum n_i\, d_i^2}$$

where n_i and d_i are the number and diameter of the droplet of the class i.

The average droplet diameter d_{32} is obtained from the sum of the volumes of all the spherically shaped droplets, divided by their surface area. This definition is due to J. Sauter [80], who as early as 1926 introduced it in his study on fuel gasification in carburetors. Thus d_{32} is known in the English-language literature as the Sauter mean diameter.

The following relationship exists between d_{32} and the interfacial area a per unit liquid volume:

$$a \equiv \frac{A}{V} = \frac{\sum \pi\, d_i^2}{\sum (\pi\, d_i^3/6)} = \frac{6\,\varphi_{\mathrm{v}}}{d_{32}}$$

The process relationship for the target quantity d_{32} (or for a) can be formulated either with extensive or intensive quantities. The difference lies in the choice of the process parameter. The dispersion characteristic formulated with *extensive* quantities uses as the process parameter the extensive quantity stirrer speed and leads, assuming a given geometry (stirrer type; D/d, H/d, h/d = const), to the following dependence (the index d indicating the physical properties of the dispersed phase, no index indicating the physical properties of the continuous phase):

$$d_{32} = f\,(d;\, \varrho_{\mathrm{d}},\, \varrho,\, \mu_{\mathrm{d}},\, \mu,\, \sigma,\, \varphi_{\mathrm{v}};\, g\Delta\varrho,\, n)$$

From this follows the pi set:

$$\{d_{32}/d,\, We,\, Re,\, Fr',\, \varrho_{\mathrm{d}}/\varrho,\, \mu_{\mathrm{d}}/\mu,\, \varphi_{\mathrm{v}}\}$$

where $We \equiv \varrho\, n^2\, d^3/\sigma$ represents the Weber number.

Most process characteristics were represented in this pi space. For the six-blade turbine stirrer it was correspondingly found that:

$$d_{32}/d = \mathrm{const}\; We^{-0.6} f\,(\varphi_{\mathrm{v}}) \tag{26}$$

and most researchers have found that const = 0.05 – 0.08, see [1].

The relationship $(d_{32}/d)\; We^{0.6}$ = const can be derived with the help of the Kolmogorovs theory of isotropic turbulence (see Section 1.4). However, this relationship only applies, if the boundary conditions for the presence of isotropic turbulence are fulfilled, i.e., if the flow in the tank is turbulent ($Re > 10^4$), both liquids possess comparable viscosities, and the volume fraction of the dispersed phase is low.

Droplet disintegration is caused by the kinetic energy of the turbulence eddies. Eddies whose size λ corresponds approximately to the droplet diameter d_{32}, i.e. $\lambda \approx d_{32}$, have the strongest dispersing action. For $\lambda \gg d_{32}$ the droplet is carried along by the flow and thereby is hardly deformed, whereas for $\lambda \ll d_{32}$ the eddies possess insufficient kinetic energy to cope with the surface tension.

Details concerning the effects of coalescence and of φ_v on d_{32}, and of the effect of viscosity and of the stirring duration are given in [1]. Here, the evaluation of the droplet size distribution is also presented which uses the *intensive* quantity P/V instead of n.

5.3. Stirrer Power for Dispersion

In dispersing of L/L systems, the same power characteristics apply as with mixing in homogeneous material systems, if for the liquid density the average density of the dispersion

$$\varrho_m = \varrho + \varphi_v \, \Delta\varrho$$

and for the viscosity of the liquid the weighted geometric mean of the viscosities of both phases

$$\mu_m = \mu_d^{\varphi_v} + \mu^{(1-\varphi_v)}$$

or the physically more understandable expression

$$\mu_m = \frac{\mu}{1-\varphi_v}\left(1 + 1.5\,\varphi_v \frac{\mu_d}{\mu_d + \mu}\right)$$

is used.

5.4. Scale-Up of the Dispersion Processes

Starting from the dispersion characteristic $d_{32}/d \propto We^{-0.6}$, Equation (26), it follows that the scale-up criterion is:

$$(d_{32}/d)\, We^{0.6} = d_{32}\,(\varrho/\sigma)^{0.6}\,(n^3\, d^2)^{0.4} = \text{idem} \qquad (27)$$

From this the following scaling-up rule for the stirrer speed is obtained:

$$n_T = n_M\, \mu^{-2/3} \qquad (28)$$

If in the scale-up criterion the expression $n^3\, d^2$ is replaced by the equivalent expression for the turbulent flow range, $P/\varrho V$, the following expression is obtained

$$d_{32}\,(\varrho^{0.2}/\sigma)^{0.6}\,(P/V)^{0.4} = \text{idem} \qquad (29)$$

which states, that the average droplet size and thus the same volume-related interface area a is maintained, if, both on a small or large scale, the same stirrer power per unit volume is utilized.

5.5. Mass and Heat Transfer Upon Dispersion

Mass transfer in the L/L system proceeds via the boundary layer of the continuous phase, which surrounds the droplet. The mass-transfer coefficient k_c (index c denotes the continuous phase) depends on the flow conditions, the droplet size, and the physical properties of the surrounding continuous phase. It can be assumed, that mass transfer inside the droplet proceeds via diffusion.

In 1961 Calderbak and Moo-Young [81], carried out a comparative investigation on the mass and heat transfer in bubble columns and columns with sieve or sintered plate spargers in the G/L and L/L phase systems. They arrived at relationships, which apply for both phase systems ($k_L = k_c$). Both k_L and also the film heat-transfer coefficient h only depended upon the material properties and not upon the flow condition (relative velocity). Two process relationships were obtained, which apply for different diameter ranges for the dispersed phase. For particle sizes $d_p \leq 2.5$ mm, the droplet-bubble surface did not oscillate; the flow between the two phases was hindered. Thus so-called rigid spheres were involved. On the other hand for $d_p \geq 2.5$ mm, the dispersed phase moved freely under the influence of the acceleration due to gravity and free convection between the two phases could occur. The corresponding process relationships are as follows:

Bubble/droplet diameter $d_p \leq 2.5$ mm; rigid spheres:

$$Sh = 0.31\,(Ar\,Sc)^{1/3} \quad \rightarrow \quad k_L\left(\frac{\varrho^2}{\mu\, g \Delta\varrho}\right)^{1/3} \propto Sc^{-2/3}$$

$$Nu = 0.31\,(Ar\,Pr)^{1/3} \quad \rightarrow \quad \frac{h}{c_p\,\varrho}\left(\frac{\varrho^2}{\mu\, g \Delta\varrho}\right)^{1/3} \propto Pr^{-2/3}$$

Bubble/droplet diameter $d_p \geq 2.5$ mm; oscillating bubble surfaces:

$$Sh = 0.42\,Sc^{1/2}\,Ar^{1/3} \quad \rightarrow \quad k_L\left(\frac{\varrho^2}{\mu\, g \Delta\varrho}\right)^{1/3} \propto Sc^{-1/2}$$

$$Nu = 0.42\,Pr^{1/2}\,Ar^{1/3} \quad \rightarrow \quad \frac{h}{c_p\,\varrho}\left(\frac{\varrho^2}{\mu g \Delta\varrho}\right)^{1/3} \propto Pr^{-1/2}$$

This fundamental study, which also serves as an excellent example of the analogy between mass and heat transfer, only gives the k_L or k_c values for the flow conditions in tray columns, i.e., for flow processes, in which the final droplet or bubble size is achieved within or in the immediate neighborhood of the sparger.

Schindler and Treybal [82] investigated the mass transfer in the L/L system in continuously operated stirred tanks with and without baffles. They established that k_c increased according to $k_c \propto (P/V)^{0.55}$ and that in a tank without baffles the stirrer for the same power realized a ca. 2.5-fold k_c compared with the tank with baffles. This and the effect of the residence time of the droplets in the stirred tank are the reasons for the positive effect of droplet coalescence and redispersion, which renew the boundary layer of the surrounding phase.

Keey and Glen [83] used the same experimental apparatus as [82], but worked with a ternary material system and used other methods for determining the volume-related interfacial area. However, they could satisfactorily confirm the above results. If the dependence $k_c = f(P)$ is approximated with $k_c \propto (P)^{0.5}$, it follows:

$$k_c = 1.55 \times 10^{-4}\,P^{0.5}$$

or with respect to the tank volume used ($V = 11.0$ L):

$$k_c = 1.7 \times 10^{-2}\,(P/V)^{0.5}$$

where k_c is in cm, and P in W or P/V in W/m^3.

For theoretical approaches see [1].

6. Dispersion in Gas – Liquid (G/L) Systems

In this operation, generally termed gas – liquid contacting or simply gassing, the aim is to increase the interfacial area between the gas and the liquid. This important operation is utilized in the chemical industry in hydrogenation, chlorination, oxidation, etc. In fermentations and in aerobic wastewater purification, supply of oxygen is one of the most important process engineering operations. Stirred tanks and bubble columns are typically used for this operation in the chemical and pharmaceutical industries, whereas flat ponds and recently high cylindrical tanks ("towers") are being used in wastewater purification.

The target quantity of the gassing process is the absorption rate in the G/L system. The absorption rate is directly proportional to the interfacial area between the gas phase and the liquid phase. The limiting factor is the diffusion of the dissolved gas through the liquid side of the boundary layer, which can be affected by the thickness of the layer only to a limited extent. A substantial intensification of mass transfer is only possible by increasing the G/L interfacial area: gas sparging by means of stirrers, nozzles, sintered or perforated plates, etc., should therefore effect a dispersion of the gas into fine bubbles.

Unlike the mass transfer in the S/L system (see Section 5.5), the G/L interfacial area is not constant, but depends in addition to the process parameters also on specific physical properties of the liquid treated, which significantly contribute to the size of the gas bubbles.

6.1. Physical Fundamentals of Mass Transfer

The driving force in this process is the deviation from the thermodynamic equilibrium and thus the chemical potential μ. The mass transfer ceases, when the equilibrium is reached at the G/L interface.

With the two-film theory of Lewis and Whitman [84] two conditions are postulated for this transfer process:

1) On either side of the phase boundary two stationary laminar fluid layers (films) are formed with thicknesses δ_G and δ_L, through which the gas can only pass by diffusion.
2) At the interface a thermodynamic equilibrium immediately arises. This means that at the phase boundary the equilibrium concentration, i.e., the saturation concentration prevails:

$$c* = c_s = f\,(i, T, p)$$

The two-film theory therefore enables the chemical potential difference $\Delta\mu$ to be replaced by the concentration difference Δc of the gas between the gas phase and the phase boundary, as well the phase boundary and the liquid phase, respectively. However, the concentration change from one side of the phase boundary to the other is then discontinuous.

This discontinuity is eliminated using Henry's law

$$p = Hy\, c$$

where Hy is the Henry constant, a function of material conditions and temperature. Taking this into account, the concentration change from phase to phase is continuous [1].

According to the first postulate of the two-film theory, an overall mass transfer occurs. There are two mass transfer coefficients, k_G and k_L, which are defined by their corresponding film thicknesses δ and diffusion coefficients D:

$$k_i \equiv D_i/\delta_i$$

The mass transfer equation formed with the mass flux j_m then reads:

$$j_m \equiv G/A = k_G\,(p - p*) = k_L\,(c* - c) \tag{30}$$

Typical diffusion coefficients D for gases are approximately a factor of 10^4 to 10^5 higher than for liquids, hence $D_G \gg D_L$ applies and according to Equation (30) also $k_G \gg k_L$, i.e., resistance to gaseous transport $1/k_G$ is negligible compared with $1/k_L$.

The only important exception, in which $k_G \ll k_L$ has to be assumed, is the chemisorption of a gas component from a gas mixture in flue gas scrubbing, since here depletion of the gas to be adsorbed is involved and in addition the concentration of the gas is already zero at the interface due to the extremely fast chemical reaction. Since gas scrubbing is not normally carried out in stirred tanks, this exception will not be considered here.

Thus Equation (30) becomes:

$$j_m \equiv G/A = k_L\,(c* - c) \rightarrow G = k_L A\,\Delta c \tag{31}$$

The mass flow G of the gaseous component is directly proportional to the mass transfer coefficient on the liquid side, k_L, the mass exchange surface A and the concentration difference Δc.

The exchange surface A is unknown and with k_L is itself a function of the physical properties and the process-related parameters. This is the reason why the target quantity in mass transfer is, as a rule, a product of these two quantities. $k_L A$ is the target quantity in surface aeration:

$$k_L A = G/\Delta c \tag{32}$$

If gas – liquid contacting takes place in the liquid volume, e.g., in stirred tanks and in bubble columns, a quasi-uniform material system is usually assumed (same bubble density in each volume element) and the mass flow G is related to the (ungassed) volume of liquid V:

$$G/V = k_L a\,\Delta c \quad k_L a = \frac{G}{V\,\Delta c} \qquad a \equiv A/V \tag{33}$$

Therefore $k_L a$, the volume-related liquid-side mass-transfer coefficient, rather than k_L is the aim of most investigations in this area.

$k_L a$ is usually referred to in the English-language literature by the term "volumetric liquid-side mass-transfer coefficient", which is not strictly correct, because the mass transfer is not recorded by a volumetric measurement, but merely is related to the volume. Here, the term "volume-related liquid-side mass transfer coefficient" will be used.

For temperature dependence of $k_L a$ as well the saturation concentration c_s of the gas in different liquids, see [1]. This source also contains information on different measuring methods for $k_L a$: Unsteady-state methods (using oxygen electrodes or manometric method), steady-state methods (sulfite method, hydrazine method, hydrogen peroxide method).

6.2. Mass-Transfer Characteristics in the G/L System

Most of the measurements concerning mass transfer in G/L systems were carried out with the turbine stirrer, because very early it became apparent, that stirrers with resistance due to their shape are the most suitable for dispersing gas. (There are indeed measurements, which prove that turbine stirrers with twelve paddles are energetically more favorable than those with six paddles [94]). In several publications differently

designed hollow stirrers have been utilized. Hollow stirrers are also excellent gas dispersers in addition to their ability of sucking the gas in.

Under given geometric and material conditions the following quantities are involved:

Target quantity: $k_L a \equiv G/(V\,\Delta c)$

Process parameters: P/V and $v \equiv q/S$

where q is the gas throughput and S is the cross-sectional area of the working space.

Already in 1979 VAN'T RIET [85] evaluated and compared 76 publications in which the turbine stirrer had been utilized as gas disperser. He derived the following dimensionally formulated mass-transfer relationships:

a) Ion-free water (complete coalescence):

$$k_L a = 2.6 \times 10^{-2}\,(P/V)^{0.4}\,v^{0.5} \pm 20-40\,\% \qquad (34)$$

b) Ion-containing water (suppressed coalescence):

$$k_L a = 2.0 \times 10^{-3}\,(P/V)^{0.7}\,v^{0.2} \pm 20-40\,\% \qquad (35)$$

The boundary conditions in both cases were: $V = 0.002-2.6\,\mathrm{m}^3$; $P/V = 0.5-10\,\mathrm{kW/m}^3$. The constants applied for P/V in $\mathrm{W/m}^3$, v in m/s, and $k_L a$ in s^{-1}.

According to the above findings, the stirrer power must be formulated as P/V and the gas throughput as $v = q/S$. The following relevance list:

$$\{k_L a;\ \varrho,\ \mu,\ D,\ \sigma;\ P/V,\ \mathrm{v},\ g\}$$

is therefore the starting point from which the following set of pi numbers results:

$$(k_L a)^* \equiv k_L a \left(\frac{\nu}{g^2}\right)^{1/3};\ (P/V)^* \equiv \frac{P/V}{\varrho\,(\nu g^2)^{1/3}};$$
$$\mathrm{v}^* \equiv \frac{\mathrm{v}}{(\nu g)^{1/3}};\ Sc \equiv \frac{\nu}{D}\quad \sigma^* \equiv \frac{\sigma}{\varrho\,(\nu g^4)^{1/3}}$$

6.2.1. Sorption Characteristics in Coalescence-Bound Systems (Water)

JUDAT [86] compared the results of twelve publications in the area of coalescing systems. The measurements were carried out both under unsteady-state (nine publications) and under steady-state (hydrazine method; three publications) test conditions, in which the geometric parameters were varied within extraordinarily wide boundaries: $d = 0.05-3.1$ m; $D = 0.15-12.2$ m; $H = 0.15-6.1$ m; the volume of the test tank varied in the range $V = 2.5$ L to $906\,\mathrm{m}^3$! The geometric numbers ranged from $D/d = 2.0-7.3$; $h/d = 0.3-1.1$; $H/D = 0.5-1.0$ and the gas throughput number $B* = (\pi/4)\,\mathrm{v}* = 0.01-1.5$. This test material could be described with an accuracy of $\pm 30\,\%$ just with the two intensity quantities $(P/V)*$ and $B*$, see Figure 16:

$$(k_L a)* = 9.8 \times 10^{-5}\,(P/V)^{*0.40}\,(B*^{-0.6} + 0.81 \times 10^{-0.65/B*})^{-1} \qquad (36)$$

Figure 16. Sorption characteristic $k_L a* = f\ \{(P/V)*,\ B*\}$ for fully unsuppressed coalescence (water – air) [86]; Superficial velocity of the gas $B* \equiv (\pi/4)\,\nu*$

If the results obtained from Equation (36) are compared with those from Equation (34), it turns out that Equation (36) provides ca. 30 % higher values than Equation (34), the values from (34) being on the bottom edge of the $\pm 30\%$ spread. Thus the simpler Equation (34) can be used and 30 % added.

Measurements of $k_L a$ in low viscosity sugar, starch, and fermentation solutions performed in laboratory ($D = 0.2$ m; $V = 8$ L) and pilot-plant fermenters, for which $H/D = 1.3-1.7$ and one to three turbine stirrer on the same shaft were utilized [105] were evaluated within the same dimensionally analytical framework. It was found that:

$$(k_L a)* = 7.9 \times 10^{-5}\,(P/V)^{*0.34}\,\mathrm{v}^{*0.39} \pm 30\,\%$$

6.2.2. Sorption Characteristics in Coalescence-Inhibited Systems

The addition of some inorganic electrolytes (so-called "structure builders") or some organic compounds (e.g., aliphatic alcohols) to water changes the water structure in aqueous solutions, see [92]. This effect strongly influences the coalescence of primarily produced gas bubbles and is comprehensively treated in [1], Section 4.10.

Information about the sorption characteristics of coalescence-inhibited systems was obtained using hollow stirrers (type: three-edged stirrer) in geometrically similar stirred tanks in scales $\mu = 1-5$ with the material system 1 N sodium sulfite solution [88], [89]. In self-aspirating hollow stirrers v is not a freely selectable process parameter! The dependence $(k_L a)* = f\,(P/V)*$ is shown in Figure 17. The sorption characteristic was:

$$(k_L a)* = 1.1 \times 10^{-4}\,(P/V)^{*0.8} \tag{37}$$

In respect of P/V it corresponded well with the process relationships of VAN'T RIET (Eq. 35):

$$k_L a = 2.0 \times 10^{-3}\,(P/V)^{0.7}\,v_G^{0.2}$$

or from ROBINSON and WILKE [92]:

$$k_L a \propto (P/V)^{0.9}\,v^{0.39}$$

in which the gas throughput (i.e., the superficial velocity v) was a freely selectable process parameter.

Figure 17. Sorption characteristic $(k_L a)* = f\,(P/V)*$ for self-aspirating hollow stirrers for full coalescence suppression, [88], [89]
$H* \equiv H - h$ = liquid height above the stirrer

6.2.3. Sorption Characteristics in Non-Newtonian Material Systems

With the advance of fermentation technology (production of antibiotics, citric acid, essential amino acids, etc.) interest has increased in the supply of atmospheric oxygen to more viscous and non-Newtonian liquids. Numerous publications are dealing with these material systems, see [1]. Here, only one by HENZLER [91] is presented. He correlated the same experimental results as JUDAT [86] by using a different dimensionless frame:

$$Y' \equiv \frac{k_L a}{v}\left(\frac{\nu_{eff}^2}{g}\right)^{1/3} = f\left(X' \equiv \frac{P}{Vv}\frac{1}{\varrho g}\right)$$

where Y' is the sorption number for bubble columns, see [100], while X' represents the ratio of the mechanical power of the stirrer to the hydraulic power of the gas throughput. In this frame also measurements with aqueous glucose and millet mash (Newtonian liquids) and with aqueous CMC solutions (non-Newtonian liquid, showing pseudoplastic and viscoelastic flow behavior) are presented (see Fig. 18).

Figure 18. Sorption characteristics of some Newtonian and non-Newtonian liquids in the evaluation framework according to HENZLER [91]; the incorporation of the *Sc* number is not necessary. Tank with turbine stirrer ($d/D = 0.24-0.4$; $H/D = 1$)

6.3. Stirrer Power in Gassed Liquids

In mixing vessels gas is continuously introduced into the liquid either via a tube or by a sparger

centrally positioned under the stirrer. The task of the stirrer is to break up the gas flow into very small gas bubbles, i.e., to produce a G/L dispersion.

Knowledge of the stirrer power in a gassed liquid is necessary for dimensioning the stirrer drive. Otherwise, the stirrer power also determines the phase boundary per unit volume in the gas – liquid system and thereby the mass transfer itself.

The power P of a given stirrer under given installation conditions in an *ungassed* liquid depends upon the stirrer diameter d, the physical properties of the liquid (ϱ and ν) and the stirrer speed n. In a *gassed* liquid the following process parameters must be added to this list: the gas throughput q and the acceleration due to gravity g, since a material system with density differences $\Delta\varrho$ is only effective as $g\Delta\varrho$ under the influence of gravity. In contrast to those of the liquid phase the physical properties of the gas phase (ϱ' and ν') are certainly negligible, but not a priori the surface tension σ and the, up to now, unspecified physical properties S_i, which regulate the gas bubble coalescence and control the size of the gas bubbles. The smaller the stable gas bubble size in the system, the lower the tendency of gas bubbles to leave the system, thus the higher the gas content in the liquid and the lower the density of the material system. The relevance list is here, for given geometric conditions, much more extensive as compared with expression for the stirrer power in a pure liquid (see Section 2.3.2):

$$P;\ d;\ \varrho, \nu, \sigma, S_i;\ n, q, g\Delta\varrho \tag{38}$$

and is compressed by means of dimensional analysis to the following set of six pi numbers:

$$\{Ne, Q, Fr', Re, We, S_i*\} \tag{39}$$

The meaning of Ne and Re is the same as in the power characteristic for a homogeneous system (see Fig. 10) the other abbreviations stand for the following pi numbers:

Gas throughput number	$Q \equiv \frac{q}{n\,d^3}$
Froude number	$Fr' \equiv \frac{n^2\,d\,\varrho}{g\Delta\varrho}$
Weber number	$We \equiv \frac{n^2\,d^3\,\varrho}{\sigma}$
Coalescence numbers	S_i^*

At low process pressures the quotient $\Delta\varrho/\varrho$ in Fr' becomes $\cong 1$, whereupon the extended Froude number Fr' reduces to $Fr \equiv n^2 d/g$.

Zlokarnik [93] found no effect of We and S_i* in measurements with a turbine stirrer of conventional design in pure liquids and in glycerol-water mixtures (coalescing material systems!). Surprisingly, the Froude number also had no effect on Ne in the industrially interesting range of $Fr > 0.65$, so that for $Re \geq 10^4$ the power characteristic could just be described by $Ne(Q)$ (Fig. 19). The process equation is:

$$Ne = 1.5 + (0.5\,Q^{0.075} + 1600\,Q^{2.6})^{-1} \tag{40}$$

Validity range: $Q \leq 0.15$; $Fr \geq 0.65$; $Re \geq 10^4$ and $D/d \geq 5$.

For an extended D/d range ($D/d \geq 2.2$) and $Re > 10^3$ see [1].

Judat has comprehensively extended this work. In [94] $Ne(Q)$ relationships are given for different stirrer types, namely for perforated disk stirrers with twelve holes, for three-wane propeller stirrers with a pitch $\alpha = 26°$, for pitched-blade stirrer with a pitch $\alpha = 45°$ and for conventional turbine stirrers with different numbers of blades $i = 6$; 12; 18; 24. The measuring range of Q was extended for turbine stirrers to $Q \approx 1.0$. It was shown that in the Q range 0.2 to 1.0 Equation (40) did not apply; with increasing Q, Ne decreases further.

For the power characteristics of non-Newtonian fluids see [1], [95], [96].

6.4. Flooding Point

The most important boundary condition for the application of the proposed power characteristic $Ne(Q, Fr, D/d, h/d)$ is given by the upper boundary value of the gas throughput number Q. At a particular stirrer speed each stirrer can only disperse a particular maximum gas throughput in the liquid. Upon exceeding this value the stirrer is "flooded" by gas, i.e., it is completely enveloped by gas and is incapable of dispersing it.

In dispersion processes in gas – liquid systems gas cushions are developed in so-called suction regions behind the surfaces of the stirrer hit by the flow, whereby the pumping ability of the stirrer for the liquid (circulation flow)

Figure 19. Power characteristic $Ne(Q)$ of a turbine stirrer in the air-water system ($H/D = 1$, $h/d = 1$) [93]; the curve corresponds to Equation (40)

ceases. Thereby the discharge of the gas dispersion is also diminished, the gas cushions becomes ever larger and at a particular value of the gas throughput number $Q_{\max}$ the stirrer is flooded with gas.

The $Q_{\max}(Fr)$ dependence for the turbine stirrer with six paddles (Rushton turbine) is given by the process equation

$$Q_{\max} = 0.19\, Fr^{3/4} \quad 0.1 < Fr < 2.0$$

For the $Q_{\max}(Fr)$ dependencies of the perforated disk stirrers with twelve holes, for three-wane propeller stirrers with a pitch $\alpha = 26°$, for pitched-blade stirrer ($\alpha = 45°$) and for conventional turbine stirrers with different numbers of blades $i = 6$; 12; 18; 24 see [94] or [1].

In order to obtain information on the efficiency $P/q_{\max}$ of these types of stirrer, the results $Ne(Q)$ and $Q_{\max}(Fr)$ were linked to one another by introducing two new dimensionless numbers:

$$\frac{Ne\,Fr}{Q_{\max}\,(D/d)} \equiv \frac{p}{q_{\max}\,\varrho\, g\, D} \quad \text{and}$$

$$\frac{Q_{\max}\,Fr^{1/2}}{(D/d)^{5/2}} \equiv \frac{q_{\max}}{g^{1/2}\,D^{5/2}}$$

The relationship between these numbers is shown in Figure 20 and proves that turbine stirrers perform best even with respect to the efficiency of gas dispersion. In this regard the twelve-blade turbine stirrer is clearly superior to the usual six-blade turbine stirrer.

In gassing viscous liquids, the flooding point was only clearly observable up to a viscosity of approx. $\nu = 3 \times 10^{-4}$ m^2/s. At higher viscosities a gradual change in the flow conditions occurred, whereby a clear definition of the maximum gas throughput was rendered impossible [96]. Measurements were performed with a turbine stirrer ($d/D = 0.3$) in aqueous glycerol solutions.

6.5. Special Gas – Liquid Contacting Techniques

In this section a few special stirrer types and nozzles will be shortly presented.

6.5.1. Hollow Stirrers

Hollow stirrers are designed such that they can utilize the suction, which develops behind the flowed against stirrer surfaces, for sucking gas into the liquid (see Fig. 7).

The use of hollow stirrers is gaining importance particularly in working under high system pressure, because in this way an isobaric reaction can be carried out without additional gas supplying device. For working with a pure gas (e.g., 99.9 % N_2 or with H_2 in hydrogenations) the manometric (pressure gauge) method can also be used for the determination of the overall reaction kinetics, see [89] and [1]. The pressure drop in a stirred tank as a result of gas absorption is compensated by further supply of reaction gas from a storage vessel, whose weight or pressure loss is monitored as a function of time.

Figure 20. Efficiencies $(P/q_{\max})*$ for different stirrer types [94]

In [87], [88] the power and throughput characteristics of three-edged stirrers in the turbulent flow range (water-air system) are presented, which were determined under the geometric conditions in the scale range of $\mu = 1-5$. They show that the state of flow in the turbulent range ($Re > 10^4$) is unequivocally described by the Froude number:

$Ne = f_1(Fr)$ and $Q = f_2(Fr)$

There are stirring operations in chemical engineering in which a large gas throughput is involved (e.g., purging of volatile compounds from a liquid), for which a minimization of stirrer power input is desirable. The condition for which $P/q = \min$ can be obtained from the process characteristics $Q = f_1\,(Fr)$ and $Ne = f_2\,(Fr)$, if the Ne, Q, and Fr numbers are combined in a way that a dimensionless expression for P/q arises:

$$\frac{NeFr}{Q} \equiv \frac{P}{q\,d\,\varrho g} = f_3\,(Fr)$$

The course of this function shows that two operating ranges exist:

1) For $Fr \leq 10$, $Ne\ Fr/Q = \text{const}$ applies, i.e. $P/q \propto d$. In this range P/q increases directly proportionally with scale. (In case of a scale-up of $\mu = 1:10$, the full-scale device requires a ten-fold stirring power for the same gas throughput!)
2) For $Fr \geq 10$, hollow stirrer operate even less economically, since here $NeFr/Q$ increases approximately proportionally with Fr: i.e., $P/q \propto d^2$!

Here, the gas throughput and the stirrer power must be decoupled from one another, by feeding a fast rotating turbine stirrer from underneath by externally compressed gas.

However, there are many reactions in gas–liquid systems, in which a high gas throughput is not required e.g. because the microkinetics are rate-determining. In such circumstances the hollow stirrer due to its dual role as stirrer and gas pump is the stirrer type of choice, particularly in high-pressure reaction engineering.

6.5.2. Surface Aerators

Surface aeration is little used due to the unfavorable interfacial area volume ratio. For many years, the only important exception was the provision of oxygen for municipal sewage treatment

plants, until volume aeration with fine air bubbles became established in this area.

Turbine surface aerators are designed as liquid-conveying devices (turbines). They are arranged in the liquid surface. The design data were realized with classical turbine stirrers (Rushton turbine), which were arranged in the liquid surface as surface aerators [97].

The power characteristic of turbine stirrer as surface aerators shows that it has to be formulated as $Ne(Fr)$ as is to be expected. For a number of formerly common types of surface aerators these characteristics are found in [97].

The sorption characteristic of turbine stirrers as surface aerators in a given material system (water; Sc and $\sigma* = \text{const}$) is represented by the process equation [98]:

$$(k_L A)* = 1.41 \times 10^{-4}\, Fr^{1.205}\, Ga^{0.115}$$

Application range: $Fr = 0.02 - 0.34$; $Ga = (1.5 - 200) \times 10^9$; $\sigma* = 3317$; $h/d = 0.2$

The target number is:

$$(k_L A)^* \equiv \frac{G}{d^3\,\Delta c}\left(\frac{\nu}{g^2}\right)^{1/3}$$

and the process numbers are:

$$Fr \equiv \frac{n^2\,d}{g} \quad \text{and} \quad Ga \equiv \frac{Re^2}{Fr} \equiv \frac{d^3\,g}{\nu^2}$$

Through coupling the power and sorption characteristics information can be obtained as how the efficiency $E \equiv G/P$ (kg O_2/kWh) of this aerator class behaves upon scale-up to an industrial scale:

$$E^* \equiv (k_L A)^*\, Ne^{-1}\, Fr^{-1.5} \equiv \frac{G\,d^{0.5}}{P\,\Delta c}\,\varrho\,\left(\nu^2\,g^5\right)^{1/6} = f\,(Fr, Ga)$$

An evaluation of the comprehensive experimental data in [98] shows that the relationship $E* \propto Fr^{-0.35}$ exits, i.e., $E*$ decreased with increasing Fr. Therefore industrial-scale aeration should operate with the smallest possible Fr value.

If a turbine stirrer, operated as a surface aerator on a laboratory scale, was scaled up to an industrial scale and if a favorable Froude number was selected for the full scale realization, the effect of the scale-up on the efficiency E can be predicted from the above presented relation for $E*$:

$$Fr = \text{idem} \quad \rightarrow \quad E^*\,Ga^{-0.115} = \text{const} = \frac{G\,d^{0.155}}{P\,\Delta c} = \text{const}$$

For $\Delta c = \text{const}$ it follows that:

$$E_T = E_M\,\mu^{-0.144}$$

where the scale-up factor $\mu \equiv d_T/d_M$.

In a scale-up of $\mu = 4\,(10)$ the efficiency of the industrial turbine surface aerator will amount to 80 % (70 %) of that of the model; the efficiency of a stirrer surface aerator thus decreases slightly with increasing scale [98].

6.5.3. Gas Spargers and Injectors

Sintered glass or ceramics plates and perforated metal plates are classical gas spargers (dispersers) for bubble columns. Static mixers and nozzles became available with the emergence of biological wastewater purification. They all realize gas dispersion *directly* and the hydrodynamics in the processing space is solely determined by the rising bubble swarm. A stirrer, on the other hand, produces gas dispersion *indirectly* via an intensive shear flow of the liquid, which disperses the gas continuum as gas bubbles. In other words: for the stirrer to produce gas bubbles, the whole liquid content must be kept in motion!

There are numerous publications from the field of chemical reaction engineering, which deal with mass transfer in bubble columns [99]. They consistently report that the volume-related mass-transfer coefficient on the liquid side $k_L a$ at not too high superficial gas velocities ($v \leq 200$ m/h) is directly proportional to the superficial velocity v:

$$k_L a \propto v \rightarrow k_L a/v = \text{const} \tag{41}$$

This is an important information when one realizes that $k_L a \equiv \frac{G}{V\,\Delta c}$ and the superficial velocity is $v \equiv \frac{q}{S}$. Then the following expression is obtained:

$$k_L a/v = \frac{G}{V\,\Delta c} \times \frac{S}{q} = \frac{G}{q\,H\,\Delta c} = \text{const} \tag{42}$$

Figure 21. Bayer injectors [99] Left: injector 8/14; Right: slot injector

where the liquid volume V is the cross-sectional area S of the processing space multiplied by the liquid height H: $V = SH$.

In contrast to Equation (41), the proposition of Equation (42) is intellectually understandable, the rate of absorption G being directly proportional to the gas throughput q (number of gas bubbles), the liquid height (residence time of the gas bubbles) and the concentration difference Δc.

Spargers. For spargers with the gas throughput as the only process parameter, the target quantity $k_L a/\mathrm{v}$ should only depend upon the sparger type. In this case dimensional analysis provides only one target number which is called the sorption number Y:

$$Y \equiv \frac{k_L a}{\mathrm{v}} \left(\frac{\nu^2}{g}\right)^{1/3} = f\,(Sc,\, Si_i^*,\, \text{sparger type}) \tag{43}$$

The sorption number may depend on physical properties of the system (Sc, Si_i^*) and on the sparger type. For pipe and dome aerators it is possible to calculate roughly with the numerical value $10^5\,Y \approx 4-5$ [99]. For the Kenics aerator this value is higher, $10^5\,Y \approx 6$, because a gas – liquid dispersion is produced, whose momentum protects it against constriction as a result of the liquid entrainment of the bubble flue (airlift pump!).

Two-Component Nozzles. There are two types of two-component nozzles: ejectors and injectors. The *ejectors* are liquid jet aspirators, which operate according to the Venturi principle and with their propulsion liquid jet in the mixing space (diffuser) attain a substantial pressure drop on the gas side. Vacuum is commonly produced by water ejectors (vacuum pumps) in the laboratory and by steam ejectors on an industrial scale.

In an *injector* practically no pressure drop is produced, the power of the propulsion liquid jet

being utilized in the mixing chamber for producing an energy-rich gas – liquid dispersion. The free jet of the gas – liquid dispersion requires this energy to mix into the surrounding liquid, before a strong bubble coalescence takes place due to the high gas bubble density.

In contrast to spargers, the injectors possess a second freely selectable parameter in addition to the gas throughput q_G, the liquid throughput q_L, which would bring about the process characteristic q_L/q_G. In analogy to stirring, instead of q_L/q_G a dimensionless number was proposed [99], [101] which took the power of the propulsion jet into consideration: P_L/q_G. This number assumes knowledge of the pressure drop characteristics of the propulsion jet nozzle $Eu_L \equiv \frac{\Delta p_L\, d^4}{\varrho_L\, q_L^2}$ and is named the gas dispersion number, X:

$$X \equiv (P_L/q_G)^* \equiv \frac{P_L/q_G}{\varrho_L\,(\nu g)^{2/3}}, \text{ where } P_L = \Delta p_L\, q_L. \tag{44}$$

For injectors it therefore follows:

$$Y = f\,\{(P_L/q_G)*, Sc, Si_i^*, \text{type of injector}\}$$

Only two injectors of Bayer AG (Leverkusen, Germany) have been investigated in this framework (see Fig. 21). The larger of them, the so-called "slot injector" (see Fig. 21, right side) forms the basis of Bayer's tower biology for the aerobic wastewater treatment of chemically polluted effluents.

In Figure 22 the sorption characteristics of the slot injector are shown as a function of the degree of coalescence of the medium (water). This is varied via the addition of common salt.

Figure 22. Dependence of sorption characteristics $Y = f\,(X)$ of the slot injector upon the system proneness to coalescence (NaCl concentration) [99]

Figure 23. Efficiency E (kg O_2/kWh) of the oxygen uptake with a slot injector [99]
Boundary conditions: $G/V = 0.1$ kg O_2 m^{-3} h^{-1}, $T = 10\,°C$, $c\ (O_2) = 0$ mL/m^3; efficiencies of the air compressor $\eta_G = 0.60$ and the water pump $\eta_L = 0.75$ are taken into consideration

Figure 24. Maximum attainable efficiency E_{max} for slot injector
Operation conditions: $G/V = 0.1$ kg O_2 m^{-3} h^{-1}, $T = 20$ and 40 °C, $c\ (O_2) = 1$ mL/m^3. The scale on the curves gives the oxygen concentration in the off-gas in vol %

If the injectors are utilized for supplying activated sludge with atmospheric oxygen in a biological wastewater purification plant, it is of particularly interest that they realize the oxygen uptake G (kg O_2/h) with a high efficiency E (kg O_2/kWh). Since the injectors possess two degrees of freedom (q_G and q_L), an optimization procedure is used, which is shown in Figure 23 for the slot injector. The fact that the E value increases with increasing liquid height H, is caused by a longer residence time, during which the gas bubbles release oxygen to the liquid, thereby increasing the oxygen utilization. Thus for a given oxygen uptake G a smaller gas throughput and hence a lower compression power P_G is necessary.

Since the sorption characteristic $Y = f(P_L/q_G)*$ and the pressure drop characteristics Eu_L and Eu_G are known as a function of the throughput ratio q_L/q_G, an infinite number of value pairs of $\{q_L, q_G\}$ can be found for each required oxygen uptake G (e.g., 1 kg O_2/h) under given boundary conditions (liquid height H, concentration of dissolved oxygen to be maintained, e.g., 1 mL/m^3), which fulfill these requirements. However, only one of them satisfies this requirement with a minimum total power ($\sum P = P_G + P_L$) and hence maximum efficiency E. This is illustrated in Figure 24.

The plot of $E_{max}(H)$ in Figure 24 shows how the efficiency and the oxygen utilization behave with liquid height. The fact that 40 °C is more favorable than 20 °C, can be explained by the increase in Sc and hence k_L in this temperature interval not yet being nullified by the simultaneous decrease of Δc, due to $c_s(T)$.

1. Introduction

Thick mixtures with viscosities >10 Pa s do not lend themselves to simple mixing with a small turbine or propeller stirrer in a large pot. The high viscosity may arise from a high concentration of solids in a slurry, the high viscosity of the matrix fluid itself, or by interactions between the ingredients.

With high viscosity fluids, the mixing Reynolds number ($Re = D^2N/\mu$) is likely less than 100. Thus, mixing occurs by viscous forces alone, and turbulence plays no part. The viscous forces cause either shear flow or elongational flow. Relative motion of an agitator stretches and deforms the material between itself and the vessel wall. As a layer of fluid gets stretched into thinner layers, and then undergoes reorientation, the striations become ever thinner until homogeneity is achieved. Likewise, the shear forces tear away at solid agglomerates and cause their disintegration.

Many mixers have been independently developed for specific process applications, and then their usage has been extended to other processes involving somewhat similar, but difficult mixing tasks. The agitated tubs used for kneading bread dough evolved into horizontal vessels that could more readily be tilted for emptying. The design evolved into double arm mixers, which in turn led to a variety of mixing blades tailored for other end uses as these double arm mixers began to be used for adhesives, gums, putties, rubber solutions, pigment dispersions, and a host of other products.

The very difficulty in defining precisely the consistency of these various doughs, pastes, and thick slurries has fostered a wide art of mixer design, rather than a sound scientific approach. Consequently, mixers are generally classified more by their mechanical features than by the process function for which they may best be suited.

With solids present, producing a homogeneous distribution is frequently only part of the mixing task. It may also be necessary to reduce the particle size of the solids, even down to submicrometer size, to achieve the desired end product, such as pigment dispersion. However, not all products need such fineness; for example, the fiber glass that is introduced into molten plastic should be uniformly distributed with minimum breakup.

High viscosity mixers usually have a limited high shear zone to minimize overall heat buildup, and depend upon the impeller also circulating all of the mixer contents past the high shear zone. Stagnant zones can exist, material may ride on blades and be kept out of the mixing region, and pockets of unmixed components may be carried through continuous process equipment since there is a sharp drop off of transmitted shear away from the shear creating device. High velocity impellers may be ineffective since they may create an isolated hole in the mass without producing any circulation, particularly with pseudoplastic materials.

When mixing a minor component (of either a solid or another viscous fluid) into a continuous phase viscous fluid, two kinds of mixing action may be required. The first is distributive mixing where interfaces are maintained intact, but the minor component is distributed uniformly throughout the mass. The second is dispersive mixing where the interfaces are broken up. With two-phase fluid systems, the differences bet-

ween distributive and dispersive mixing has been described by OTTINO and coworkers [1–3].

ERWIN [4], [5] has measured distributive mixing in single screw extruders. Dispersive mixing has been evaluated for a variety of flow conditions by RUMSCHEIDT and MASON [6], [7], GRACE [8], and HAN [9]. ERWIN [10] concluded that extensional flow is the most efficient of plain strain laminar flows.

The degree of distributive mixing for a two-phase mixture can be characterized by the relative increase in interface area or number of striations per unit length. ERWIN and coworkers [2], [3] have shown that mixing increases linearly with the average total shear strain applied. They have also shown that mixing efficiency in single screw extruders was increased significantly by reorientation of the interface, such as with mixing pins. Also, poorer mixing occurs in laminar shear flows when the ratio of the viscosity of the disperse phase to the continuous phase increases.

For a given shear field, there is a maximum viscosity ratio beyond which a liquid droplet cannot be broken up. KARAM and BELLINGER [11] have shown that breakup is easier when the interfacial tension (σ) is low, the viscosity of the continuous phase (μ_c) is high, and the radius (r) of the droplet is large. Their plot of reduced shear rate vs. viscosity ratio ($\mu_r = \mu_d/\mu_c$) is reproduced here as Figure 1. Thus, when extremes in viscosity ratio are encountered, real fine dispersions cannot be achieved in simple shear fields alone.

For viscous fluid – fluid mixtures, the efficiency of a mixer in theory can be determined from a combination of three factors: critical capillary number at which breakup occurs, the time required for this breakup, and the number and size of the resulting drops. The capillary number is the ratio of the viscous forces to the interfacial forces. The critical capillary number in shear flow goes through a minimum at a viscosity ratio of 1, and above 4, simple shear flow is no longer effective.

With a hyperbolic flow, the critical capillary number is lowered. The time for breakup increases as the viscosity ratio is increased. As the capillary number is increased above the critical value, the number of fragments produced increases sharply at first, but then becomes constant. Thus, the relative dispersion efficiency of different mixing devices should be compared only under similar parameters of viscosity ratio, initial drop size, continuous phase viscosity, and interfacial tension. The number and size of the fragments produced versus time would be a reasonable measure of dispersion efficiency.

Equipment for viscous mixing is characterized by small clearances between impeller and vessel walls, high power per unit volume, and relatively small volume. Because of probable heat buildup, impeller speeds may have to be very slow. Intermeshing blades or stators may also be required to keep the material from cylindering on the rotating impeller.

A smearing blade profile may be required where dispersion is important, whereas a scraping profile may be desired if heat transfer is critical. A mixing action which causes material to work against itself can be used to advantage.

Ease of discharge, and ease of cleaning between batches are important requirements for paste mixers. Mere bottom drainage is frequently inadequate, in which case the vessel may need to be dumped.

Mixing in general has been treated in the two-volume edition *Mixing–Theory and Practice*, and in particular for viscous mixing in the chapter by IRVING and SAXTON [12]. Similar topics are also covered by PAHL [13]. The triennial European Conferences on Mixing [14], although concentrating more on multiphase dispersion and reaction in turbulent mileau, do also have some papers on viscous and non-Newtonian mixing phenomena.

Power. For viscous mixers with agitators that sweep near the vessel wall, the power drawn depends primarily on the viscous drag of the agitator rather than on the pumping effect incurred in circulating the material to the high shear zone. For scale up, the following approach may be taken:

Shear rate (DN/t)
Shear area (DL)
Shear stress = (shear rate) · (viscosity)

$$\alpha \left(\frac{DN}{t}\right) \mu$$

Force = (shear stress) · (shear area)

$$\alpha \left(\frac{\mu DN}{t}\right) (DL)$$

Figure 1. Effect of viscosity ratio on dispersion [11]
Reduced shear rate $\frac{\gamma_b \mu_c r}{\sigma}\left(\frac{1.19\mu_r+1}{\mu_r+1}\right)$ where
σ = interfacial tension; μ_c = viscosity, continuous phase; μ_d = viscosity, dispersion phase; $\mu_r = \mu_d/\mu_c$; r = drop radius; γ_b = shear rate at breakup

$$\text{Torque} = (\text{force}) \cdot (\text{radius})$$

$$\alpha \left(\frac{\mu D^2 L N}{t}\right) D$$

$$\text{Power} = (\text{torque}) \cdot (\text{speed})$$

$$\alpha \frac{\mu D^3 L N^2}{t}$$

for dimensional similarity, with both clearance (t) and agitator length (L) proportional to diameter D:

$$\text{Power} = \alpha \mu D^3 N^2$$

Actually, for most very viscous mixtures, the viscosity μ is not constant, and is usually shear thinning, with an effective viscosity depending upon the $(n-1)$ power of speed, where n is the power index number of the fluid (the slope of shear stress vs. shear rate on logarithmic coordinates).

Figure 2. Anchor mixer

2. Batch Mixers

Single Stirrer Mixers. Thick pastes can be handled in a variety of simple batch mixers in which the agitator is in close proximity to the vessel wall. With an anchor blade (Fig. 2), the proximity of the blade to the vessel wall improves heat transfer while providing gentle ag-

itation. Use of single or double helical blades (Fig. 3) provides not only the scraping action at the wall but also an end-to-end turnover of vessel contents. A single helical auger may be used inside of a draft tube with reliance on flow back up the annulus caused by the pumping action of the central auger. Some mixers also employ stators attached to the vessel wall that are in close proximity to the multi-arm central agitator, such as shown in Figure 4.

Figure 3. Helical blade mixer

Change Can Mixers. Change can mixers are vertical batch mixers in which the mixing vessel can readily be separated from the agitator. Agitation is usually provided by two planetary mixing blades (Fig. 5). Separate cans permit accurate weighing of the ingredients prior to mixing, easy transport of the mixture to the next process operation, and easier cleaning of the mixer between batches.

Figure 5. Change can mixer (Chas. Ross & Son)

Figure 6. Vertical mixer (Baker Perkins)

With most smaller change can mixers, such as used in ink and pigment manufacture, the mixing head is raised from the can either by tilting or vertically. Change can mixers also have permanently mounted agitator elements with the can raised for mixing. The latter type (Fig. 6) is used extensively for mixing solid propellants.

A variety of blade shapes has evolved to provide for thorough mixing of the can contents. The blades are usually intermeshing and pitched to provide some axial movement. The can may be rotated on a turntable to bring all material past the mixing head, or the planetary gear mounting may rotate around a fixed can. The can may also tilt for dumping, as shown in Figure 7.

Change can mixers are available generally in the 1 – 500-L size, with the propellant mixers up to 4000 L.

Double Arm Kneading Mixers. These mixers consist of two tangential or overlapping horizontally mounted mixing shafts rotating in a rectangular trough with the bottom curved in two half cylinders to match the sweep of the mixing blades (Fig. 8). Several mixing blade shapes are available (Fig. 9). Most common is the Sigma Blade (Fig. 9A), with unequal arms angled and unequal rotating speeds to impart randomness to the mixing action. Material is swept arount the bottom and divided as it is brought down over the saddle ridge between the half cylinders.

Figure 7. Intensive mixer with withdrawable agitator and tilting discharge (Eirich)

Dispersion of agglomerates is improved with blades that provide compressive shear forces against the trough shell with a wedged shape face (Fig. 9B) rather than a scraping blade profile. Heat transfer is promoted bvy using a cored blade and a scraping profile on the blade front (Sigma Blade, Fig. 9A). Shredded action can also be imparted (Fig. 9C), or cutting action (Fig. 9D).

If the mixed contents are free draining, or if a heel of the batch can be left behind without impairing the quality of succeeding batches, the mixer may be emptied through one or two gates or valves on the bottom. However, the usual pro-

Figure 8. Double arm kneading mixer (Baker Perkins)

cedure is to tilt the mixer for emptying. The mixer can also be provided with a screw discharge mounted in the saddle section (Fig. 10). The screw is reversed during the mixing stage to assist mixing.

Double Arm mixers are available in size ranges from 1 L to 5 m^3. As size is increased, rotational speeds are generally reduced. Power inputs range from 0.02 – 0.5 kW/kg. A typical 500-L mixer might run with a front blade speed of 30 rpm and be supplied with a 40 kW drive motor.

Ram Mixers. The Banbury Type mixer (Fig. 11), is capable of extremely high power inputs, up to 6 kW/kg, in size ranges from small laboratory to 500 kg. A compression ram is used to confine the mixture between the tight fitting rotors and vessel walls. The masticating action is most useful for mixing elastomers and plastics. The mixed product is dumped through a front or bottom discharge door. The relatively large shafts permit very high torques. As with all very viscous mixing operations, batch temperature rise may be very rapid and may be the factor limiting cycle times. At 1 kW/kg, temperature rise per minute could readily reach 30°.

High Intensity Mixers (Fig. 12) utilize a high speed bottom mounted blade to impart high shear and to establish a vortex flow in the vessel. The bottom blade scoops the batch upward at peripheral speeds of 40 m/s. Blade impact is effevtive in reducing agglomerates and aids intimate dispersion. Energy input is high (up to 200 kW/m^3), and these high intensity mixers are frequently paired with a slower speed, larger batch cooler of similar design. These mixers are particularly suited for rapid mixing of powders and granules with minor amounts of liquids, such as when plasticizer is added to poly(vinyl chloride) (PVC) resin. The dry PVC granules are heated by the blade action within a few minutes, after which the plasticizer is added and rapidly penetrates the pores of the PVC particles to provide a homogeneous feed mixture for

downstream processing. Other uses are for removing volatiles from pastes under vacuum, and for dissolving solids in liquids. Sizes range from 1 – 1100 L.

Figure 10. Screw discharge batch mixer (Werner & Pfleiderer)

Figure 11. Banbury mixer (Farrel)

A somewhat similar mixers, shown in Figure 13, utilizes a horizontal impeller. Incorporated into the mixer is an optical pyrometer to indicate when the desired energy has been imparted by sensing the inside product temperature. Since a high level of energy can be supplied, the mix cycle time is quite short.

Plow Mixers have plow elements on a horizontal shaft rotating in a cylindrical vessel (Fig. 14). After charging, the smooth fitting cover is closed, and rapid shaft rotation hurls material into the free space. Addition blending is provided by the impellers plowing through the solids bed. If agglomerates are present, an additional small high speed chopper may be added.

Figure 14. Plow mixer (Littleford Bros.)

Cone and Screw Mixers (Fig. 15) are used for a variety of low-energy blending applications ranging from dry powders to pasty materials. An orbiting screw rotates about its own axis and also around the center line of the cone shaped vessel

near the wall to provide bottom to top circulation. The screw is reversed to aid discharge of pasty materials. Screw and cone mixers, available in capacities from 40 to 20 m^3, work equally well when only partially filled.

Figure 15. Cone and screw mixer (Day Mixing)

Mullers (Fig. 16) can be used for powders and pastes if the latter are not too soupy or too sticky. The mullers smash agglomerates as they rotate in a circular patch inside the round pan. An attached plow brings material progressively into the path of the mullers. Typical applications are for mixing putty and clay pastes, battery paste, and chocolate coatings. A continuous muller variant consists of two rotating sets of muller wheels operating with some overlap in a figure-eight pan.

Figure 16. Muller (National Engineering)

Roll Mills provide a very high localized shear by drawing the mixture into the nip of closely spaced parallel rolls. The viscosity of the matrix can be held high to aid dispersion because of the extensive surface area for heat transfer. The material passing through the nip is returned to the feed point by rotation of the rolls. A temperature differential between the rolls frequently causes the material to selectively adhere to one of the rolls, as it does when blending rubber stocks. Although there is little distributive mixing as the material passes through the nip, there is a rotary motion of the bead of material immediately upstream of the nip. In addition to blending rubber stocks and dispersing carbon black, roll mills are used extensively in grinding and dispersing inks and pigment pastes.

3. Continuous Mixers

Although some of the batch mixers can be modified for continuous processing, the generally broad residence time is usually not conducive to

Figure 17. Kenics static mixing features

the best product uniformity. However where the component feed streams can be adequately and accurately metered, several mixers have been developed specifically for continuous processing. Continuous mixers generally consist of a closely fitted rotating element within a stationary housing with flow through the unit controlled to prevent by-passing.

3.1. Motionless Mixers

Longitudinal and transverse distribution of components can be obtained in flowing systems by placement of stationary flow redistribution devices, called motionless or static mixers, in the flow stream. Many proprietary designs have evolved, all of which divide and displace a laminar streamline from one portion of the conduit cross section to another. Examples of static mixers are shown in Figures 17, 18, 19. The Kenics mixer shown in Figure 17 consists of alternate right and left handed twisted ribbons arranged in sequence. The Ross ISG (Fig. 18) uses four drilled holes through solid sections between axially displaced cavities to redirect flow streamlines both radially and peripherally. The Sulzer SMV mixer (Fig. 19) has stacks of corrugated lamellae with open crossing channels. Most other static mixers involve variations of these three basic types with features that may permit easier fabrication or installation.

Figure 18. Ross ISG mixer
A) Assembly; B) Individual element

PAHL and MUSCHELKNAUTZ [15] have presented both mixing and pressure drop comparisons for these and other static mixers. In general, the more divisions, the better the homogenization. However, the smaller the passageways

Figure 19. The Sulzer mixer
A) Sulzer mixing elements; B) Operating principle of the Sulzer mixing element

and the larger the fraction of conduit cross section occupied by metal, the higher the pressure drop. Choice of the best static mixer for a particular application involves a compromise based on energy and space available. Static mixers are of most value for distributive, rather than dispersive fluid mixing applications. With no moving parts, there are low investment, operating, and maintenance costs.

3.2. Single Screw Mixers

The use of continuous mixers has increased considerably with the expansion of the plastics industry. End products of greater usefulness depend upon the uniform incorporation of a multitude of additives, stabilizers, antioxidants, fillers, reinforcing agents, as well as alloys and blends of differing base polymers. The base polymer resin needs to be in the melt stage to permit uniform distribution of the additives. Since the thermal conductivity of polymers is generally very low, melting is best accomplished by work energy rather than by heat transfer through a vessel wall. The screw extruder shown in Figure 20 consists of a cylindrical barrel with a helical screw. The root diamater of the screw is smaller in the feed zone. The dry ingredients, sometimes having been premixed in a batch mixer, are conveyed by the rotation of the screw. As the root diameter of the screw is increased, the solids are compressed and caused to melt primarily by friction against each other and against the barrel wall. The homogenized product is forced through some shaping element, such as dies for film, sheet, profile, or strands for subsequent pelletizing. Since the final mixture is extremely viscous (10 – 5000 Pas effective viscosity) the pressure drop through the die is high; consequently, a pressure flow back toward the feed occurs down the screw channel, which partially offsets the drag flow caused by the conveying action of the screw. Cross-channel flow occurs, and most of the mixing is accomplished by the time the last bit of polymer has melted. A further homogenization can be achieved by using a mixing head at the end of the screw, such as shown in Figure 21. The mixing heads operate by forcing all of the product over confined flow paths, or reorienting the elongated laminar layers. The capacity of an extruder is determined primarily by the power which can be supplied. Single screw extruders can be equipped with large gears and thrust bearings to operate with high torque. Although the majority of extruders are in the 25 – 200 mm diameter range, large extruders do exist for tasks such as polyethylene homogenization: these are considerably larger and are equipped with up to 4000 kW drives. Comprehensive extruder texts are Rauwendaal [15], Bernhardt [17], and Tadmor and Gogos [18].

Figure 21. Mixing promoters for single screw extruders

Some variants of single screw extruders are offered which enhance mixing by greater reorientation of the product as it progresses down the barrel. The KoKneader (Fig. 22) achieves this by three rows of teeth projecting inward from the barrel wall, which intermesh with the interrupted screw flight as the screw reciprocates once each rotation. The passage of the teeth, as shown in Figure 23, provides an intimate kneading action [19].

Reorientation of the laminar striations to improve distributive mixing is accomplished in the Transfermix (Fig. 24) and the Cavity Transfer mixer (Fig. 25) as material being conveyed in the screw flights or pockets is repositioned into complementary flights or pockets in the barrel.

When starting with solid resin to be melted and mixed, the overall conversion of mechanical energy of a single screw extruder into useful work is improved by segregating the melt as it is formed by use of some type of barrier screw, as is shown in Figure 26. A channel of slightly decreased outer diameter and increasing width between the flights of the main channel enables the melt to be accumulated free of the unmelted solids and enables the solids to be more effectively compressed and fused between the decreasing width screw channel and barrel.

3.3. Twin Screw Mixers

With two screws inside a figure-eight barrel, a variety of mixing effects can be created depending on whether the screws co-rotate or counter-rotate, and whether they are tangential or they intermesh. Twin-screw extruders are used for a broad variety of products, but their most extensive usage is in polymer processing. They lend themselves to good control of temperature

Figure 22. KoKneader mixer (Buss AG)

and residence time, and for staging of sequential events such as degassing or further additive addition at the appropriate stage down the barrel. Like the single-screw extruders, twin-screw extruders are used for generating the pressure required for discharging the product through forming dies for profile or stranding.

With the co-rotating intermeshing twin screw depicted in Figure 27, there is complete wiping of all surfaces. Intense mixing action can be created with the use of kneading paddles of similar cross section, but arranged axially in an offset fashion. The kneading paddles create a series of compression – expansion zones [20] while forwarding the mixture down the barrel. Such twin-screw mixers have been built from 15 mm diameter laboratory size to huge commercial machines of 889 mm diameter.

With counter-rotating tangential screws (Fig. 28) the cross mixing between screws provides much distributive mixing and striation reorientation [21]. The large surface exposure is also of benefit in devolatilizing applications.

Robust rotors can be used in short barrels to provide a continuous variant (Fig. 29) of the Banbury-type intensive-fluxing mixer. The mixting action is a combination of intensive shear material between the rotors, and a rolling action of the material itself.

Counter-rotating intermeshing twin-screw extruders (Fig. 30) are very effective in pressure generation since axial back flow is severely restricted by the intermeshing.

Mixing of solids is the distribution of at least one solid component through another. The mixing of granular solids is a widely employed process in chemistry, pharmacy, food manufacturing, the ceramics industry, and ore beneficiation.

Mixing solids is much more difficult than mixing liquids (stirring), where in most cases just a few material constants are enough to characterize the components of the mixture. The mixing process with solids is influenced by disperse properties such as grain shape, grain size, particle-size distribution (gradation), and friction in the bulk material. A comprehensive survey of equipment and methods was published by RIES [1].

Basic mixing mechanisms are not sufficiently well known. This is manifest in the variety of existing mixer types and in the continual appearance of new and novel mixers on the market. In principle, there are two limiting cases:

1) The mixing of powders depends so heavily on product qualities that every product requires its own mixer design.
2) Mixing is a universal process and can be carried out in any apparatus, provided that the material is placed in motion.

Limiting conditions are often more important in mixer selection than the actual mixing process. The following points are often crucial:

1) Explosion safety
2) Cleanability
3) Simultaneous use of the mixer as a silo or interim storage bunker
4) Controlled addition of liquid

1. Mixedness

To assess a mixing process, it is necessary to define a suitable measure of mixedness; and this measure must be kept in mind in all tests, also in regard to the sampling conditions.

Considerable space in the literature on solid – solid mixing has been devoted to the definition and determination of mixedness. Definitions differ so much that any attempt to comprehensively present the state of the art would necessarily end in confusion. The reviews on mixedness are, unfortunately, of little assistance in clarifying the situation [2–5].

One of the reasons for the differences is the measure of mixedness presented in a particular review is usually only appropriate for the mixing problem described in the review. Thus FAN et al. introduce elements of packing structure into the definition of mixedness by considering the number of contact points between particles of the two components [6–12]. Another reason is that theoreticians often find it easier to develop their own statistical measure of mixedness on the basis of some reasonable assumption than to follow up the lines that had been pursued by others.

The first critical evaluation of methods describing the state of a mixture appeared in 1965 [13]. An analysis of 37 statistical expressions describing the state of a mixture is presented in [14]. Although this description of mixedness is unchallenged, it frequently is too complex for the practicing chemical engineer or industrial chemist.

1.1. Theoretical Variance

All mixing operations, whatever their purpose, have in common that they attempt to even out a nonuniformity in the composition or other properties (e.g., color). Such mixing always involves relative motion between particles, for which energy must be expended.

Total equalization within a mixture leads to ideal mixing, which is symbolized by, say, a checkerboard. In powder mixtures, ideal mixing occurs only in the rarest of cases. The best possible result in technical powder mixing is "random mixing." Particles are randomly mixed when the probability with respect to composition or some property is equal in all regions of the mixture or samples from it. In real mixtures, the properties always differ from the ideal value, i.e., nominal concentration, P. This departure is used in the definition of mixedness. Since it is not critical whether the real values depart upward or downward from the nominal value, the mean absolute value of the deviation can be introduced as a measured value. But the absolute value is difficult to handle mathematically, and so the mean-square deviation, the *variance*, has come to be used.

The variance characterizes the mixture as a whole and thus requires a knowledge of the characteristic property everywhere in the mixture. Such knowledge can be gained only by making theoretical assumptions about the state of mixing or by determining the property everywhere in the mixture. Theoretical variances σ^2 must therefore be distinguished from variances determined on the mixture in practice, which are based on a finite number of samples. To prevent confusion, empirical variances are represented by s^2 (see Section 2.2).

The property X can normally be determined only by a measurement procedure of finite precision. Even when the properties really are completely identical in the samples, the measured values thus depart from the nominal value and contribute to the variance [15]:

$$\sigma^2_{\mathrm{tot}}(t) = \sigma^2_{\mathrm{M}} + \sigma^2_{\mathrm{Z}} + \left(1 - \frac{g}{G}\right) \cdot \sigma^2_{\mathrm{syst}}(t) \tag{1}$$

The variance is thus composed of three terms: σ^2_{M}, the variance of the precision of measurement; σ^2_{Z}, the variance of random mixing, which represents the optimal case for granular materials; and σ^2_{syst}, the variance characterizing the mixture, which itself can be used to assess the mixedness.

$$\sigma^2_{\mathrm{syst}}(t) = \frac{1}{1 - \frac{g}{G}} \left\{\sigma^2_{\mathrm{tot}}(t) - \sigma^2_{\mathrm{M}} - \sigma^2_{\mathrm{Z}}\right\} \tag{2}$$

The factor g/G is the ratio of the particle size (e.g., mean particle mass g) and the sample size (e.g., sample mass G). If the sample and particle sizes G and g are assumed to be equal, the measured property depends only on the particle component, not on the state of mixing. The parameter σ^2_{syst} can no longer be measured in the selection of a sampling method. Evaluation of Equation (2) requires a knowledge of σ^2_{M} and σ^2_{Z}.

1.2. Variance of the Precision of Measurement

The precision can usually be determined only through preliminary tests. The variance of the precision must be estimated on the basis of a sufficiently large number of measurements of the selected sample quantity G. Care must be taken that the measurement technique corresponds closely to reality; for example, preparation steps must be included. What is more, a check must be made to see how strongly the precision of measurement depends on the value of the property itself. Often all that is known for a measurement technique is the maximum error. In such cases, a rough estimate for use as a starting point is $\sigma_{\mathrm{M}} \approx \Delta X_{\max}/3$.

1.3. Variance of Random Mixing

If the property to be measured correlates directly with a concentration measure of the mixture, then the variance of random mixing can be calculated from the sampling condition [16], [17]. There are a number of special cases:
Constant particle number n; number concentrations x, p

$$\sigma_{\mathrm{Z}}^2(x) = \frac{p(1-p)}{n}$$

Constant particle number n; mass concentrations X, P

$$\sigma_{\mathrm{Z}}^2(X) = \frac{P(1-P)}{E(G)} \cdot (P \cdot g_{\mathrm{y}} + (1-P)\, g_{\mathrm{x}})$$

where g_{x} is the mean grain mass of component (X) weighted with the distribution q_3^{x} of component (X); g_{y} is the mean grain mass of component (Y) weighted with the distribution q_3^{y} of component (Y), and $E(G)$ is the mean value of sample mass G.

Constant sample property G, mass concentrations X, P

$$\sigma_{\mathrm{Z}}^2(X) = \frac{Q^2 P}{G} \cdot \int_0^1 \frac{g(Q_3^{\mathrm{x}})}{(Q - P Q_3^{\mathrm{x}})^2} \mathrm{d}Q_3^{\mathrm{x}}$$

$$Q = 1 - P$$

where $g(Q_3^{\mathrm{x}})$ gives the individual grain property of component (X) as a function of the undersize $Q^{\mathrm{x}}{}_3$. The smallest grain of component (X) with gradation function Q_3^{x} is larger than the largest grain of component (Y).

Constant sample property G, mass concentrations X, P

$$\sigma_{\mathrm{Z}}^2(X) = \frac{P}{G} \cdot \int_0^1 g(R)\, \mathrm{d}R - \frac{2P^2}{G} \int_0^1 (1-R) \int_0^R \frac{g(\xi)}{(1-\xi)^2} \mathrm{d}\xi \mathrm{d}R \tag{3}$$

where $g(R)$ gives the individual grain properties of components (X) and (Y) as functions of the oversize R. Components (X) and (Y) have the same gradation, $Q_3^{\mathrm{x}} = Q_3^{\mathrm{y}} = 1 - R$.

Figure 1. Axial concentration profile in a batch mixer at times t_0 and $t > t_0$. L = length of the mixer, P = theoretical concentration, $P(r_{\mathrm{j}}, t)$ = expected concentration in position r_{j} at time t

1.4. Mixedness versus Time

The random variance σ_{Z}^2 and, if the precision is dependent of concentration, the variance σ_{M}^2 are independent of time. The time dependence of the total variance $\sigma_{\mathrm{tot}}^2(t)$ is then given by the time variation of the systematic deviations alone.

At time $t = t_0$ let the components in a mixer be completely separated. With the passage of time, the spatial concentration distribution will become uniform. The changes in the system can be described in terms of variations along one

coordinate (Fig. 1). In a practical mixing device, the material particles sshould not undergo any predetermined changes of position. Changes of position should be stochastic. This type of motion is treated by the theory of random processes. MÜLLER [18] has shown that mixing, as a stochastic process without aftereffect, can be described by Kolmogorov's second differential equation. Equation (3) is valid if there is no selective transport of the constituents:.

$$\frac{\partial P(r,t)}{\partial t} = \frac{\partial^2}{\partial r^2}\left[D^*(r,t)\cdot P(r,t)\right] \tag{3}$$

where $D^*(r,t)$ is the dispersion coefficient, initially dependent on position and time. If we further assume that $D^*(r,\ t) = D^* =$ constant, then Equation (3) becomes Fick's second law of diffusion:

$$\frac{\partial P(r,t)}{\partial t} = D^*\cdot\frac{\partial^2 P(r,t)}{\partial r^2} \tag{4}$$

If only batch mixers are considered, the solution can be given as a Fourier series [18]:

$$P(r,t) = P + \frac{2}{\pi}\sum_{\mu=1}^{\infty}\frac{\sin\mu\cdot\pi}{\mu}\cos\mu\cdot\pi\frac{r}{L} \cdot\exp\left(-\mu^2\left(\frac{\pi}{L}\right)^2\cdot D^*\cdot t\right) \tag{5}$$

The system variance is again calculated as the average of the concentration deviations:

$$\sigma^2_{\text{syst}} = \frac{1}{L}\int_0^1\left[P(r,t) - P\right]^2\,\mathrm{d}r$$

and we obtain

$$\sigma^2_{\text{syst}} = \frac{2}{\pi^2}\sum_{\mu=1}^{\infty}\frac{\sin^2\mu\pi P}{\mu^2} \cdot\exp\left(-2\mu^2\left(\frac{\pi}{L}\right)^2 D^*\cdot t\right) \tag{6}$$

The series can be evaluated for two limiting cases:

1) At time $t = 0$ [19]:

$$\sigma^2_{\text{syst}}(t=0) = P(1-P) = \sigma_0^2 \tag{7}$$

The limiting case of the initial variance is em- bodied in Equation (6).

2) For long times, the higher-order terms ($\mu > 1$) can be neglected:

$$\sigma^2_{\text{syst}}(t) = \frac{2}{\pi^2}\cdot\sin^2(\pi\cdot P) \cdot\exp\left(-2\left(\frac{\pi}{L}\right)^2 D^*\cdot t\right) \tag{8}$$

Equation (8) shows the desired concentration dependence of the system variance. For $t\to\infty$, $\sigma^2_{\text{syst}}\to 0$ (Fig. 2). The limiting case of infinitely long times is likewise embodied in Equation (6).

Figure 2. Systematic variance $\sigma^2_{\text{syst}}(t)$ as a function of dimensionless time, for pure dispersion. D^* is the dispersion coefficient; L, the mixer length. Parameter: nominal concentration P: a) 0.5; b) 0.3; c) 0.1

Limit of Low Concentrations *P*. If component (X) is present only in small quantities, so that $P \ll 1$, the sine in Equation (8) can be expanded into a series, and all but the first term dropped:

$$\frac{\sigma^2_{\text{syst}}(t)}{P^2} = 2\cdot\exp\left(-2\left(\frac{\pi}{L}\right)^2 D^*\cdot t\right) \tag{9}$$

Here σ_{syst}/P is called the system coefficient of variation. From Equation (9) follows that, for small admixtures $P \ll 1$, the system coefficient of variation is invariant with respect to both sample size and mixture composition, satisfies the requirements of SCHMAHL [20], and is suitable as a measure of mixedness.

Figure 3. Schematic diagram illustrating the derivation of the Fokker–Planck differential equation: Δz is the displacement in time τ; $P(r)$, the concentration at point r; $\phi(\Delta z)$, the distribution function of Δz

Limit of Equal Proportions. If the two components to be mixed are present in roughly equal quantities, so that $P \approx 0.5$, Equation (8) simplifies to

$$\frac{\sigma^2_{\text{syst}}(t)}{P^2} = 2 \cdot \exp\left(-2\left(\frac{\pi}{L}\right)^2 D^* \cdot t\right) \tag{10}$$

In the region of almost equal proportions, the system variance itself is independent of sample size and mixture composition, satisfies the requirements of SCHMAHL, and is an appropriate measure of mixedness.

If the components of powder mixtures differ in grain shape, grain size, or density, stochastic mixing processes [21–28] often exhibit segregation that cannot be accounted for by the simple diffusion model with positive dispersion coefficient. The more fundamental MARKOV theories of random processes must be introduced in these cases; they lead to the so-called Kolmogorov equations. These equations were first written for statistical dynamics by FOKKER [29] and PLANCK [30] (Fig. 3).

Suppose there are a large number of spheres, mutually independent and having identical surface properties. A model system comprises small glass spheres in a matrix of large glass spheres. Let each of the spheres be set in motion. At a given time t, the concentration at a given position r has some value $P(r)$. Each of the small spheres experiences very small, rapid, stochastic collisions. Now the question is how the concentration $P(r)$ at point r changes in an interval of time. In this interval, each sphere experiences several collisions r in which the direction of motion may change. The sum of all these changes of position is called the displacement Δz. Each sphere will exhibit a different displacement Δz, even if the spheres are located at the same point r. The displacements Δz are statistically distributed with distribution function $\phi(\Delta z)$, where $\Delta z_{\max}$ is the greatest displacement that occurs. It should always be small in comparison with the mixer dimensions. Here $\overline{\Delta z}$ is the mean displacement of the spheres, that is, a mean convective transport.

Besides this convective motion, a broadening of the distribution density results from the stochastic nature of the process. The broadening is described by the mean square of the displacement $\overline{\Delta z^2}$:

$$\overline{\Delta z^2} = \sigma^2(\Delta z) + \left(\overline{\Delta z}^2\right) \tag{11}$$

where $\sigma^2(\Delta z)$ is the variance of the distribution density $\phi(\Delta z)$.

The quadratic quantity $\overline{\Delta z^2}$ is, of course, always positive. FOKKER [29] and PLANCK [30] calculated the change in concentration $P(r)$ in segment dr from the difference between the number of particles leaving dr in time τ and the number entering dr from adjacent layers in the same time. They stated the result in differential equation form:

$$\frac{\partial P(r)}{\partial t} = \frac{\partial}{\partial r}\left[P(r) \lim_{\tau \to 0} \frac{\overline{\Delta z}}{\tau}\right] + \frac{\partial^2}{\partial r^2}\left[P(r) \lim_{\tau \to 0} \frac{\overline{\Delta z^2}}{2\tau}\right] \tag{12}$$

As was already mentioned, $\overline{\Delta z}$ is the mean convective transport of the small spheres at position r in the time interval. Then $\overline{\Delta z}/\tau$ is the mean convective transport velocity. If the limit

$$\lim_{\tau \to 0} \overline{\Delta z}/\tau$$

exists, it is called the transport coefficient T and has the units of velocity. If the limit $\lim \overline{\Delta z}^2/2\,\tau$ exists, it is called the *dispersion coefficient* D^*; it has the units of area per unit time, the same as the diffusion coefficient D. The dispersion coefficient, however, is not a pure adjustment factor but a statistically derived quadratic quantity, and as such it is always positive. Then Equation (12) is written as

$$\frac{\partial P(r)}{\partial t} = -\frac{\partial}{\partial r}\left[P(r)\,T(x)\right] + \frac{\partial^2}{\partial r^2}\left[P(r)\,D^*(r)\right] \tag{13}$$

The form of this equation, which describes the time variation of concentration at positive r, matches Fick's second law of diffusion.

The analog of Fick's first law of diffusion is the mass flow rate through a unit cross-sectional area at position r at time t:

$$\dot{M}(r) = P(r)\,T(r) - \frac{\partial}{\partial r}\left(P(r)\,D^*(r)\right) \tag{14}$$

Thus the mass flow $\dot{M}$ is composed of the convective transport $\dot{M}_{\mathrm{T}}$ and the dispersive transport $\dot{M}_{\mathrm{D}}$.

Let us make the simplifying assumption that $D^*(r) = D^*$ independent of the coordinate r. If in this case the transport coefficient $T(r) = 0$, Equation (14) becomes Fick's first law of diffusion, and the dispersion coefficient D^* is identical with the diffusion coefficient D. If in the mixture under consideration the components are completely separate from each other at time t, the diffusive equalization already described takes place. The variance σ^2 of the sample concentration declines steadily from the initial state σ_0^2 until it reaches the value of the sampling error σ_z^2.

When a transport flow is present, there are two possibilities: (1) flows initially in the same direction (Fig. 4, third curve from top) and (2) flows initially in opposing directions (Fig. 4, bottom curve). If the two flows are initially in the same direction, transport at first aids the equalization of concentration, but then the diffusion flow reverses and opposes the transport until both flows are equal in magnitude. This state, which is steady, is a condition of partial mixing. At first the mixedness rapidly improves, but as demixing increases the mixedness becomes worse again. An experimental example of such qualitative segregation is found in the trials reported in [18] (see Fig. 5). The differing transport properties of iron (630 – 750 µm) and quartz (100 – 200 µm) and of iron (300 – 400 µm) and limestone (40 – 60 µm) give rise to segregation.

Figure 4. Concentration $P(r*)$ at position $r*$ and mixedness σ^2_{tot} as function of mixing time [18]

The empirical coefficients of variation reflect the prediction from the model; the diffusion and transport flows are initially in the same direction in Test 1, opposing in Test 2. For this reason, Test 1 (Fig. 5, Curve a) leads to homogeneous mixing at first but then to segregation. In Test 2, (Fig. 5,

Curve b) the stochastically homogeneous state is not reached at any time.

Figure 5. Coefficient of variation s/P versus mixing time t a) Quartz, 100 – 200 µm, and iron, 630 – 750 µm (indicator); b) Limestone, 40 – 60 µm, and iron, 300 – 400 µm (indicator), [18]

The segregations at constant dispersion coefficient, as described in the preceding section, always occur when movement of internal parts or inclination of the drum causes selective transport that opposes diffusive mixing. Segregations are seen in drum-type mixers even when no external convective transport processes are taking place. However, there is always an equalization of concentration when the transport coefficient vanishes and the dispersion coefficient is a constant. It should therefore be checked whether a position-dependent or concentration-dependent dispersion coefficient can account for the observed segregations without convective transport. For $T\ (r) = 0$, Equation (14) becomes

$$\frac{\partial P\,(r)}{\partial t} = \frac{\partial^2}{\partial r^2}\,[P\,(r)\,D^*\,(r)] \tag{15}$$

If the product is first differentiated with respect to concentration and the concentration is then differentiated with respect to r, a form comparable with Fick's first law of diffusion is obtained:

$$\dot{M}\,(r) = -\,\frac{\partial\,(P\,D^*)}{\partial P}\,\frac{\partial P\,(r)}{\partial r} \tag{16}$$

If the dispersion coefficient is taken to depend only on the concentration, the product rule can be used in differentiation:

$$\dot{M}\,(r) = -\left(D^* + P\frac{\partial D^+}{\partial P}\right)\frac{\partial P\,(r)}{\partial r} \tag{17}$$

The expression in parentheses corresponds exactly to the Fick diffusion coefficient:

$$D = \left(D^* + P\frac{\partial D^*}{\partial P}\right) \tag{18}$$

While the dispersion coefficient D^* is always positive, by hypothesis, the diffusion coefficient D can become negative when the concentration dependence of D^* supplies a sufficiently large negative derivative. Then there exists a material flow in the direction of higher concentrations; that is, the components separate.

To investigate these processes, glass spheres were mixed in a glass drum 205 mm long and 114 mm in diameter. First, dark and light spheres of the same size (d = ca. 2 mm) were used, with a fillage of 38 %; the drum rotated at 45 rpm. The mixture ratio was 1 : 1. Because the spheres were equal in size and made of the same material, the dispersion coefficient could be taken as constant independent of the concentration. The contents of the drum thus became mixed to stochastic homogeneity in a short time (≈20 min).

If small glass spheres (d = 1 mm) are mixed with large ones (d = 2 mm), the mobility of the small particles in the matrix of larger particles is estimated to be greater than in an environment of equal-sized spheres. Thus the dispersion coefficient decreases as the concentration increases. If the decline is great enough, the diffusion coefficient may become negative and the components, completely separate at first, will not mix. In the practical experiment, mixing was not observed even over very long mixing times. The contents of the drum remained separate.

If the small spheres are layered on top of the large ones, the concentration is initially uniform in the axial direction. Diffusion flow is theoretically impossible in this instance. But the equilibrium is labile if the diffusion coefficient is assumed to be negative. Because of irregularities in charging and the boundary conditions, violations can always occur, leading to concentration shifts and thus making segregation possible. Such upsets were seen close to the right and left end walls in the experiment. Radial disks near these walls showed an increased concentration of small spheres after five minutes of mixing, while the concentration in the other zones decreased. The observed segregations remained stable even over longer mixing times. The number of violations depends on the length of the mixing drum.

Figure 6. Estimated dispersion coefficient as a function of concentration P

Numerous strips could be generated by varying the drum geometry [21–23]. Symmetry in the stated form can be expected only when the initial conditions are symmetrical. If violations are imposed in the form of local increases on concentration, individual strips can even be programmed to appear at various places. Exact observation reveals that the quantity of small spheres concentrated in the stripes does not make up half the mixture contents, as at the beginning. Thus a large fraction of the small spheres must still be present in the matrix of the large spheres.

This fact can also be explained on theoretical grounds. Equation (17) shows that, for concentrations $P \to 0$, the diffusion coefficient becomes positive in every case, even when the derivative $\partial D^*/\partial P$ is large and negative. At low concentrations, then, the components are always miscible. If it is assumed, for example, that a linear relationship holds between the dispersion coefficients of the small spheres, D_1^* for concentration $P \to 0$ and $D_{2_i}^*$ at concentration $P = 1$, then the limit of segregation lies at $P_0 = 0.5$ in the first case (D_2^*) and at a higher concentration P_0 in the second case (D_2^*) (Fig. 6). If the concentration is below the limit P_0, the diffusion coefficient is positive, so that equalization of the concentration takes place by diffusion. At a higher concentration, segregation occurs. If the dispersion coefficients are in the ratio of $D_1^* : D_2^* = 1 : 2$, the concentration limit is near $P_0 = 1$; that is, at this ratio and all ratios nearer to unity, no segregation takes place.

The linear concentration dependence is merely an assumption, which could not be applied to the experimental system because of the high concentration limit of $P_0 = 0.5$. On the other hand, if the dependence resembled a normal distribution, the segregation limit P_0 lies at the steepest part of the curve, so that it may occur at much lower concentrations (Fig. 6).

Practical Consequences. The postulated concentration dependences of the dispersion coefficients are quite arbitrary. The first attempts to determine these dispersion coefficients for solids were made by Cahn and Fuerstenau [31], [32]. Unfortunately, these results cannot be applied generally. The analysis of mixing processes in terms of stochastic processes does, however, have qualitative implications. If there is a tendency to segregation because of convective transport, then according to [18], [24] the selective transport behavior can be altered by even slight changes such as the addition or removal of mixing elements.

Convective segregation tendencies should be offset, whenever possible, by a suitable choice of grain size and density [25]. If it is known that two components tend to segregate on account of negative diffusion coefficients, then the concentration dependence of the dispersion coefficient must be reduced. This is accomplished in practice by agitation in fluid-bed and centrifugal mixers. The mean free spacing between particles is large in comparison to the particle size, so that the mobility of individual particles is less dependent on the size of the surrounding particles. The success of powder mixers using the fluid-bed and centrifugal principles is due not only to the absolutely larger dispersion coefficients, but certainly also to the weaker concentration dependence. There is, however, a great danger that the ini-tially homogeneous mixtures may separate again during slow discharging and charging, because of the concentration dependence of the dispersion coefficient.

A second way to homogenize a mixture that tends to segregate is to add small amounts of liquid [33–35]. The liquid causes water to form bridges between the spheres. Because of the lesser mobility, the dispersion coefficients are much lower, but the difference in environment

and thus the concentration dependence no longer play a dominant role. Diffusive mixing is thus possible. The addition of about 1 wt % water to a charge of glass spheres 1 and 2 mm in diameter leads to a stochastically homogeneous final state after 10 min of mixing.

Figure 7. Thief for taking samples of free-flowing solids (Design: Lehrstuhl für Maschinen- und Apparatekunde [Department of Machinery and Apparatus], Freising – Weihenstephan, Federal Republic of Germany)

2. Practical Determination of Mixedness

For the theoretical mixedness (σ^2_{tot} or σ^2_{syst}) to be determined, the property must be known everywhere in the mixture. In practice, however, only a finite number of samples can be taken from the mixture. A variety of devices can be used for this purpose.

Figure 8. Sample stripper

2.1. Sampling

The simplest methods of sampling are manual ones employing sampling shovels or ladles. Sampling shovels have the top and one side open, and thus are suitable for pulling material out of a stationary bed. The sampling ladle is open only on top and is used for removing granular material from a falling stream of material. Sampling forks are good only for coarse materials such as coke.

Thieves and sampling drills are used for sampling from mixers and silos. These devices do not just sample the surface, as shovels do, but reach to depths of several meters. The thief, in simplest form, consists of a steel tube with an inside diameter of 30 – 50 mm, a wall thickness of 2 – 4 mm, and a length of 1.50 m (up to 4 m in special cases). The thief in Figure 7 is especially well suited to taking samples from free-flowing powders [36], [37]. The thief is closed and pushed into the material; sliding the tube axially along the guide rod opens and fills the chamber; the thief is then reclosed and withdrawn. For cohesive material such as moist soils, the sampling drill is appropriate. It consists of two fixed, curved plates mounted on a crosspiece. The drill is advanced into the pile by a screw motion.

The best-known sampling device for fluidized solids is the channel sampler. Normally, the channel sampler is advanced across the falling stream of material. Where the material under study is being conveyed by a belt, trough

or screw conveyor, hand sampling is more and more being replaced by automatic sampling. A simple way to take samples from a belt is to use a fixed stripper, which intercepts an exact cross-sectional area of material transverse to the conveying direction (Fig. 8).

Pendulum samplers (Fig. 9) and impact samplers (Fig. 10) find use in automatic sampling at the discharge from a belt or trough conveyor. Material is acquired at regular intervals, either transverse or parallel to the discharge direction. The pendulum sampler consists of a slotted vessel suspended from a pendulum arm. A drive rod causes it to move through the stream of material. When the sampler returns to its rest position, the material is dumped by opening the bottom gate [38], [39]. In the impact sampler, a concave impactor knocks the material out of the falling stream in the conveying direction.

Figure 9. Pendulum sampler
a) Sabo timer drive; b) Slotted vessel; c) Bottom gate; d) Actuating lever with roller

Figure 10. Impact sampler

A simple slot (Fig. 11) takes samples out of a trough conveyor. The upright slot diverts a substream of material, the sample, out of the middle of the trough. The substream remains proportional to the material flow rate as the layer depth and conveying speed vary. With a star-wheel device or a screw sampler with several slots and holes on top, fluidized material can be diverted from discharge ducts and conveying pipes [40]. The screw-type sampler can also remove a substream from a larger screw conveyor (Fig. 12). If the sampling screw rotates at a constant speed, the quantity sampled is independent of the quantity of material moved by the large screw.

Figure 11. Slot arrangement for sampling from a trough conveyor

Figure 12. Screw sampler (b) mounted on screw conveyor (a)

In many cases, the samples thus acquired are too large for measurement. The samples are remixed in the laboratory, and a sample for analysis is then taken. This procedure should be used with caution. The laboratory mixing pro-

cess must itself be monitored, since there is always a danger of segregation. It is better to use a sample divider to reduce the sample to a size that can be analyzed. Errors are also possible with this technique, but they can be determined. If, however, the particle size is small in comparison with the sample for analysis, these errors are usually negligible. Otherwise, the starting material must be comminuted until this requirement is satisfied before the sample is divided. Given these conditions, the analytical value can be assigned to the starting sample.

Figure 13. Chi-square distributions for degrees of freedom $m = 1, 2, 3$, and 4

2.2. Empirical Variance

2.2.1. Frequency Distribution and Chi-Square Distribution

If there are analytical values from k samples, the *mean-square deviation* or *variance* s^2 is

$$s^2(X) = \frac{1}{k-1} \sum_{i=1}^{k} (X_i - \bar{X})^2 \tag{19}$$

$$s^2(X) = \frac{1}{k} \sum_{i=1}^{k} (X_i - P)^2 \tag{20}$$

The second formula is used when the mixture composition P is known. If the analytical values X_i are normally distributed (an assumption that can always be made as a first approximation), the quantity $\lambda^2 = m\frac{s^2(x)}{\sigma^2(x)}$ has a *chi-square distribution*; the *number* of *degrees of freedom* (d.f.) is $m = k - 1$ when Equation (19) is used or $m = k$ when Equation (20) is used. The chi-square distribution is an asymmetrical one-dimensional probability distribution (Fig. 13). It allows a statistical assessment of the quality of the estimate s^2 in relation to σ^2, where σ^2 is the expectation of the statistically varying quantity s^2 (Fig. 14). The more d.f. and thus the greater the number of samples, the more frequently s^2 will be found close to the expected value σ^2, and the more symmetrical the frequency distribution will be.

Figure 14. Frequency distributions of s^2/σ^2 for degrees of freedom $m = 2, 3, 10, 50$, and 100

2.2.2. Confidence Intervals

If a certain probability is stated (in engineering usually 95 – 99 %, but often higher in the pharmaceutical field), the variance can be found from the chi-square distribution (Fig. 15). For example, it is possible to say with 95 % confidence that

$$\frac{s^2}{\sigma^2} \geqq \frac{\chi_u^2}{m}$$

Conversely, it can be asserted with the same degree of confidence that the true value of σ^2 (the mixedness) satisfies the relation

$$\sigma^2 \leqq \frac{m}{\chi_u^2} \cdot s^2 \tag{21}$$

In the diagram of mixedness versus time, Equation (21) gives the confidence interval for the true mixedness (Fig. 16). With 95 % confidence, the true value is lower than the stated limit.

Figure 15. One-sided 95 % confidence interval of the chi-square distribution, $m = 3$, $\chi^2_u = \chi^2_{0.05}$

Figure 16. Example of a curve of mixedness versus time. Vertical bars represent confidence intervals

2.2.3. Determination of Mixing Time

More difficult to determine than the confidence interval is the mixing time required to achieve a given mixedness σ^2_{goal}. The frequency distributions of s^2 (Fig. 14) show that, for few d.f., the number of s^2 values smaller than the true value of σ^2 is greater than the number of s^2 values greater than the true σ^2. For $m = 2$ d.f., the frequency is actually greatest for $s^2 = 0$.

The measured values of s^2 thus give the illusion of far too good a result. For the determination of the mixing time, as in the case of the mixedness, it is more correct to use the upper limit of the confidence interval.

Two cases must be distinguished in practice:

1) The mixedness σ^2_E in the mixer is clearly better than the prescribed mixedness σ^2_{goal} (Fig. 17 A). The mixing curve distinctly intersects the goal value within two time intervals, and the mixing time can be determined accurately.
2) The mixedness in the mixer σ^2_E just reaches the prescribed mixedness σ^2_{goal} (Fig. 17 B).

When the final mixedness has been reached, the measured values of s^2 fluctuate about this value in accord with their frequency distribution. In most cases, the upper limit of the confidence interval is above the mixedness target, and no clear intersection can be expected. Only when a measured value is smaller than the value s^2_u from the chi-square distribution χ^2_u does the upper limit of the confidence interval lie below the target value. This happens $(1 - P)$ times, where P is the selected probability; thus, if the confidence interval is 95 %, this happens 5 times in 100 cases.

To keep from choosing too long a mixing time, the time intervals for sampling must be held short, even though this increases the cost.

If the final mixedness is prescribed not by the mixer (σ^2_{syst}) but by the material being mixed and the precision of measurement,

$$\sigma^2_E = \sigma^2_M + \sigma^2_Z$$

then minimizing the final variance σ^2_E is often a better way to reduce the cost in the determination of mixing time. This can be done by improving the sample preparation method and the precision of measurement. If σ^2_Z is the only possible approach for improvement, the ratio of particle size to sample size can be reduced (larger samples or smaller particles).

3. Designs of Solid – Solid Mixers

Coarse mixing in solids mixers is accomplished by the continuous movement of material in the process volume. It must be possible for adjacent particles to change places. Depending on the flowability of the powders being mixed, this can be achieved through a variety of mechanisms [41] and in a variety of geometries [42]. The large number of mixers on the market can be classified under several headings [43], [44].

3.1. Tumblers

A tumbler mixer is typically a vessel in which the mixture is rotated (Fig. 18). A tumbling motion

Figure 17. Mixedness versus time curves, where the final mixedness σ^2_{E} is (A) very much smaller than the goal value σ^2_{goal} or (B) roughly equal to σ^2_{goal}. Vertical bars represent confidence intervals.

may be superimposed on the rotational motion, or components mounted on the inside of the mixing drum (internals) may force the loose material into motion. A quite simple and well-known mixer of this type is the concrete mixer. It has a capacity of 2 m^3/h on average, with mixing times of some 1 – 3 min. When rotation speeds are low, the processes of importance for mixing occur in relatively thin layers at the surface of the material bed (*cascade motion*). The slow relative motion promotes any segregation effects that occur. As the rotation speed *n* increases, the fraction of solid material in motion becomes greater. Some individual particles escape from the bed and fall freely through the empty volume onto the bed below (*cataract motion*). If a critical rotation speed *n* is exceeded, the particles are held against the drum wall by centrifugal force, and free movement and thus mixing are prevented. The scaling law for model experiments is

$$Fr = n/n_{\mathrm{crit}} = n^2 d/\mathrm{g} = \text{constant}$$

where *d* is the diameter of the mixing drum. *Fr* is the dimensionless Froude number. Tumblers have drum volumes of 2 – 100 000 L and drive powers of 0.2 – 33 kW [43].

3.2. Screw Mixers

Another class of mixers operating at relatively low Froude numbers comprises screw mixers, in which the pan or drum is stationary and a screw or screw-shaped flights or ribbons move inside it (Fig. 19). The flights move through the bed of material at tool speeds of up to 2 m/s, loosening the material and moving portions of it along. This process creates voids, which can be filled by free-flowing material. Ribbon-type impellers, usually made of flat steel strip, rotate about a horizontal axis in horizontal drums or about one or more vertical axes in pans.

Another widespread form is the screw mixer in a conical vessel (Fig. 20). One or two orbiting screw conveyors cause the material not only to rotate in the cone but also to move upward at the same time. The dual motion causes continuous mixing. ENTROP [44] has developed design diagrams for this type of mixer, giving both the mixing time and the power consumption.

3.3. Paddle Mixers

Paddle or spreader mixers operate at higher rotation speeds; the peripheral speed of the mixing tool is 10 – 40 m/s. The shaft, usually vertical, bears paddles or shovels on short end pieces (Fig. 21); plowshares or partial screw flights are also used. The mixing elements separate particles from the bed of material, setting them in motion in the air space above the charge and allowing them to mix. Angled paddles or plowshares allow an axial movement that promotes axial mixing. Because the cylinder wall and the end surfaces are accessible, liquids can be metered in with little or no crust formation. Agglomerates can be broken either with cutter heads rotating at high speed in the bed of material or with pin devices. The Eirich mixer features a pan and shovels rotating in opposite directions, thus efficiently combining the advantages of the

drum mixer and the paddle mixer. The solid material moves in continually overlapping trajectories and is thus comminuted, mulled and, if necessary, moistened.

Figure 20. Hosokawa – Nauta mixer

3.4. Pneumatic Mixers

In pneumatic mixers, the mixing action is due to the injection of air. The simplest mixer of this type is the fluid-bed mixer.

The material bed is located above a horizontal or slightly inclined perforated plate. Air flows upward through the plate and bed until the gas velocity exceeds the value required to loosen and expand the bed. Gas bubbles form and carry the particles along as they rise. At the surface, the bubbles burst, distributing the particles in the air space above the fluidized bed.

Mixers now on the market differ in the air delivery pattern, the bottom plate being divided into quadrants or segments. As mixing proceeds, one quadrant or segment after another is supplied with extra air, and in this way the bed material is caused to circulate.

Fluid-bed mixers can be used only when the individual components are not too different in sinking velocity, since otherwise segregation will occur. Another class of pneumatic mixers includes air-jet mixers of free-flowing solids. These devices consist of vessels into which gas is injected through one or more nozzles at velocities up to supersonic (Fig. 22 A). The air-jet mixer has the advantage that the mixing time is short and there is not much danger of segregation. It has the disadvantages that a high-pressure compressor must be used and that the particles are subjected to high loads in the driving jet.

Figure 21. Paddle shafts

Much gentler in operation are rotating mixers (Fig. 22 B) with internal or external rotation. These are often used to homogenize granular resins. Air is blown into an ascending pipe and conveys the granular material upward to a sep-

arating zone. Material is admitted to the central ascender through, for example, mixing slots in various regions of the bed, so that compulsory mixing takes place.

3.5. Silo Mixers

The principle of the pneumatic rotating mixer, where material portions from various regions of the bed are brought together, is used so that large silos can be used as continuous mixers, especially for large-tonnage products. The gathering of material from various parts of the silo can be monitored with, for example, concentric floor discharge openings at various heights.

Figure 22. Pneumatic mixers
A) Airmix-system fluid-bed mixer; B) Rotating mixer

3.6. Pile Mixing

When the quantities to be mixed are so large that they can no longer be stored in a single silo, mixing must be done by appropriate piling and reclaiming techniques. This form of solid – solid mixing is important for the ore and beneficiation industries [45].

1. Introduction

Separation processes are used to convert feed mixtures into two or more products differing in composition. Unit operations treated in the first part of this volume deal primarily with *diffusional separation processes* suitable for feeds that are homogeneous mixtures:

Evaporation
Distillation and Rectification
Sublimation
Liquid – Liquid Extraction
Absorption
Adsorption
Process-Scale Chromatography
Biochemical Separations (mainly diffusional processes)

These contrast with *mechanical separation* of heterogeneous mixtures, in which the product phases are already present on a microscale. These are discussed in the following articles:

Filtration
Centrifugation, Filtering
Centrifugation, Sedimenting
Hydrocyclones
Sedimentation
Dust Separation
Screening
Elutriation
Air Classification
Mineral Sorting
Magnetic Separation
Electrostatic Separation
Gravity Concentration
Dense-Media Separation
Flotation

Separation processes constitute more than half of the total equipment investment for the chemical and fuel industries. They are also widely used in pharmaceutical and food industries, in beneficiation of mineral ores and recovery of metals, in processing effluents, and in a diverse array of other industries. Separation processes may have a number of purposes, which can be loosely categorized as follows:

1) *Purification:* Removal of impurities, thereby enabling a desirable substance to be obtained at a higher level of purity; e.g., refining of sugar and treatment of drinking water.
2) *Concentration or Recovery:* Increasing the concentration of a desired substance in solution, usually by removal of a substantial fraction of solvent; e.g., production of fruit juice concentrates and recovery of metal values from effluents.
3) *Fractionation:* Separation of desired substances from one another; e.g., primary distillation of crude oil and chromatographic separations.

The first two categories imply separation of a small amount of one substance from a large amount of another. The desired products are the major and minor constituents, respectively, in the first and second processes.

2. Definitions

Most separation processes are based on the principle that different phases of matter have different compositions at equilibrium. Examples are vapor and liquid phases in distillation, and

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b03_01

immiscible liquid phases in liquid – liquid extraction. These processes achieve separation by allowing the phases to proceed toward equilibrium, hence the name *equilibration processes.*

Another category, known as *rate-governed processes*, achieves separation by means of differences in rates of transport of different species through a medium or barrier. Here the products are probably fully miscible with the feed; the separation would be destroyed by remixing them. Examples are ultrafiltration and gaseous diffusion.

A *separating agent* is added to achieve separation. In equilibration processes, this agent serves to create the second phase. The separating agent takes the form of energy or matter. Examples of *energy separating agents* are reboiler heat, which forms the vapor in distillation, and chilling or refrigeration, which causes ice to form in freeze concentration processes. Examples of *mass separating agents* are an absorbent used to separate gases and an ion-exchange resin used to desalt water. Typically, most of the utilities costs for a separation process are associated with the separating agent, e.g., the cost of steam to drive the reboiler of a distillation column or the cost of regenerating a mass separating agent for reuse. Economics and environmental restrictions usually dictate that a mass separating agent should be regenerated and reused. A separation process based upon a mass separating agent thereby requires a second, subsequent separation process.

The degree of separation achieved between two substances in different products relates to the *separation factor* between them. For equilibration processes, the separation factor α_{ij} is usually defined as the ratio of the partition coefficients (K_i and K_j) of the two species between the two phases at equilibrium ($\alpha_{ij} = K_i/K_j$). The constants K_i and K_j are the *partition coefficients* of species *i* and *j*, which are defined as the concentration of a particular species in phase 2 divided by that in phase 1. Any concentration units may be used for K_i and K_j in either phase, provided the same units are used for both species in a given phase. Phases 1 and 2 are usually chosen so that α_{ij} is greater than unity.

3. Process Configurations

Often, the species being separated is separated to an insufficient degree by a simple equilibration or by a single passage through a barrier. In these cases, the degree of separation between species can be improved by *staging* or *countercurrency*. Examples of each are shown in Figure 1. By sending the product from one contacting or stage to another and appropriately recycling intermediate products to previous stages (Fig. 1 A), the degree of separation between species in the ultimate products can be improved considerably. For a distillation operated at total reflux (infinitesimal feed and product flow), the separation factor for products from a single equilibrium stage is α_{ij}, as already noted, whereas that from *N* equilibrium stages joined countercurrently is α_{ij}^{N} (the Fenske equation) (→ Distillation and Rectification).

Continuous countercurrent contacting can be used to accomplish the same effect, as shown in Figure 1 B. Here, two phases flow countercurrent to each other through an open material such as a structured packing, which serves to create interface for mass transfer between phases. The action is analogous to that of a countercurrent heat exchanger, where the exit temperature of the hot stream can be lower than the exit temperature of the cold stream. Sometimes contactors are built with elements of both discretely staged and continuous countercurrent contacting, for example, rotating disk contactors used for liquid – liquid extraction (→ Liquid – Liquid Extraction).

Another way of improving the degree of separation achievable in a simple contacting is the *chromatographic mode.* Here a mobile phase flows along a thin, stationary phase (→ Process-Scale Chromatography).

The thinness of the stationary phase provides rapid rates of mass transfer, giving the effect of many stages or "transfer units" per unit length of the stationary phase. In elution chromatography, components of a mixture injected as a pulse at the inlet end of the contactor proceed along the stationary phase at different rates, determined by the different equilibrium distributions between phases, and emanate as a succession of isolated peaks (Fig. 2). Field-flow fractionations are rate-governed processes operated in an analogous, elution-chromatographic mode.

Figure 1. Staging and countercurrency
A) Staged mixer – settler system for solvent extraction; B) Continuous countercurrent extractor.

Figure 2. Typical output from a gas or liquid chromatograph (peak height, as sensed by any of various detection methods, vs. elution time).

A continuous staged or countercurrent contactor provides high feed capacity but generates only two products of high purity. (Intermediate products, or sidestreams, of lesser purity can also be present.) The elution-chromatography mode can separate a complex mixture into many pure peaks or products, but its inherent capacity is low because the feed is injected intermittently as pulses.

When a solid feed is used (e.g., leaching of roast and ground coffee to form coffee extract; → Liquid – Solid Extraction) or a solid mass separating agent is employed (e.g., an adsorbent; → Adsorption), movement of the solids should generally be avoided because attrition and undesirable mixing may result. *Fixed-bed processes* are commonly used (e.g., the home water softener filled with ion-exchange resin or a bed of activated alumina for drying air) when a solid feed or mass separating agent is used. A regenerated fixed-bed separation can handle a sub-

stantial feed rate but in its simplest form provides only one highly purified product, the initial effluent, before a second component leaves the bed. Among the more notable innovations in industrial separation during the past few decades have been effective ways of simulating countercurrency with fixed beds.

Yet another fundamentally different approach to separation involves migration of different species to equilibrium positions within a gradient field. One example is isoelectric focusing. These processes are inherently slow but can give separations that are not possible by other means.

4. Separation Principles

For a feed of any particlular phase condition, an equilibration separation process can be based upon formation of, or contact with, any immiscible second phase of matter. For a liquid feed, the second phase may be a gas (stripping), an immiscible liquid (extraction), or a solid (crystallization, adsorption). Equilibration may be with the bulk of the second phase or with a surface. Surface-based separation processes include adsorption, as well as foam, bubble, and emulsion fractionation (→ Flotation).

For rate-governed processes, differences in any form of transport can be exploited. These include rates of permeation through a solid membrane (→ Membranes and Membrane Separations), Knudsen diffusion in a porous medium (as used for separation of uranium isotopes in UF_6; → Isotopes, Natural), thermal diffusion, electrophoresis, or pressure diffusion.

Often, two separation principles used in concert can operate synergistically. Examples are the use of cross fields for rate-governed separation and the enhancement of relative volatility in a distillation by adding a substance that modifies the equilibrium between phases, as done in azeotropic and extractive distillation (→ Distillation and Rectification).

5. Advantages and Disadvantages of Different Separation Methods

When the same separation factors can be attained, *equilibration processes* using energy separating agents tend to be less costly than those using a mass separating agent, because of the need for circulating and regenerating the mass separating agent or else disposing of and replacing it. Similarly, when staging or countercurrency is needed, equilibration processes tend to be more attractive economically than *rate-governed* processes that give an equivalent separation factor, because equipment and energy can be utilized more efficiently in the former.

Separation processes involving a solid phase can suffer drawbacks associated with low or vanishingly small transport rates in the solid phase and with the desirability of keeping the solid phase stationary.

Certain methods of separation are better suited for certain ranges of feed concentration. In particular, *fixed-bed operations* are most effective for removing relatively dilute solutes, since the diluteness necessitates less bed volume and less frequent regeneration. Thus, adsorption and ion-exchange processes tend to be used to recover solutes from relatively dilute feeds or to remove impurities. Along this spectrum of feed concentration, extraction (with liquids) and absorption (with gases) are usually considered for a middle range of concentration, because the solvent flow rate required tends to be relatively independent of the feed solute concentration. Operational upper limits on feed solute concentration can come from the need to keep liquid phases immiscible in extraction or to avoid too large a percentage decrease of the flow rate of the feed phase. *Distillation* works well over a wide range of feed concentrations but can experience low stage efficiencies at very low solute concentrations.

Membrane separation can provide high selectivity for removing or concentrating (ultrafiltration) high molecular mass or macromolecular solutes, for removing salts from water or concentrating them (reverse osmosis, electrodialysis), and for fractionating solutes of high and low molecular mass (dialysis); (for further information, see → Membranes and Membrane Separations). Economical, high-capacity membranes that effectively remove polar organic solutes of lower molecular mass have yet to be developed, but are an area of research. The solute throughput capacity and selectivity provided by membranes can be enhanced by impregnation of the membrane with an appropriate extractant (solid-

supported liquid membranes, facilitated transport). Membrane processes are best suited for low molar solute concentrations, because providing the driving force for transport across the membrane is otherwise difficult and expensive.

Cost and Scaleup. Different methods of separation have inherently different costs. An inverse relationship tends to exist between the value of the product and the scale of production. For high-value substances produced on a small scale, a much wider range of separation techniques can be considered than for substances of lower value. Often the cost or value of a substance is influenced strongly by the difficulty of separation; therefore, for a high-value substance, utilization of a newer or less common means of separation may be necessary in order to perform the desired separation at all. Furthermore, certain separation processes (e.g., distillation, extraction) can be scaled up more readily than others. Those methods that rely on very thin phases or thin flow channels (chromatography), laminar flow (field-flow processes), or ready dissipation of heat (electrophoresis) are particularly difficult to scale up to large capacities.

Thermosensitive Product. In many cases, the feed or products are sensitive to thermal degradation, contamination, or changes due to a change in the chemical environment, such as denaturation of proteins. These constraints are particularly common in the food and pharmaceutical industries. Here, methods of separation that avoid these problems will have an advantage. To avoid thermal degradation, low temperatures and short residence times should be used. Processes that avoid heating the feed (extraction, sorption, crystallization, etc.) are advantageous; if vaporization must be used, operation under vacuum is helpful. Concerns about contamination and chemical environment limit the types of mass separating agents that can be used. For instance, in bioprocessing, many solvents have toxic effects, so precipitation and the use of solid sorbents are relatively advantageous. Similarly, proteins may denature if they are taken into a nonaqueous phase.

Processes Involving Reversible Chemical Reactions. Most industrial separations are carried out by processes that do not involve chemical reactions, because of the consumption of reagents required to accomplish the reaction, the cost of reagents needed to regenerate the original desired substance, and the need to dispose of unwanted reaction products. However, chemical complexation or association reactions (donor–acceptor, chelation, clathration, etc.) are much more readily reversible and can be used advantageously in separations to increase the selectivity among solutes or the capacity for a desired solute. Reversible chemical interactions can be implemented in extraction; sorption; ion exchange; azeotropic and extractive distillation; impregnated membranes; and foam, bubble, and emulsion fractionation. Finally, the common processes for concentrating a solute in solution by removal of solvent (evaporation, reverse osmosis, ultrafiltration, freeze concentration) incur expense in proportion to the amount of solvent that must be removed. Extraction or sorption of the solute(s) of interest can lead to concentration as well, because only a limited amount of the solvent will accompany the solute into or onto the extractant or sorbent. Reversible chemical interactions can be used effectively here as well.

6. Selection of a Separation Process

In seeking one or more appropriate methods of separating a particular mixture, the first consideration is the size of the *separation factor* likely to be attained by different methods of separation. Differences in volatility (distillation, evaporation, stripping), solubility (crystallization, extraction, absorption), charge-to-mass ratio (ion exchange, electrophoresis), molecular size and shape (adsorption with molecular sieves, crystallization, gel permeation, clathration, dialysis), and chemical reactivity can all be used for separations.

Next, whether *ordinary or extreme conditions* (very high or low pressure, very high or low temperature, etc.) are needed to obtain attractive separation factors must be determined. Methods that require excessive temperature–time combinations or result in contamination or chemical change may be ruled out by the nature of the feed or product. Also, as already noted, the *value of the substance* and the desired scale of operation can determine the number and types of alternatives to be considered, because of the varying cost of different separation methods and their suitability for scaleup. Finally, a very practical

consideration is the amount of previous *experience* with a particular process.

Among near equals, distillation has an advantage because it avoids solids, it is easy to stage and scale up, and a vast backlog of experience exists. Rate-governed processes are usually considered seriously only when the desired separation can be achieved in a single stage. Separation of uranium isotopes by gaseous diffusion is a notable exception to this generalization, however. With processes utilizing a mass separating agent, *ease of regeneration* becomes a dominant factor. Finally, as already noted, fixed-bed processes gain a compensating advantage when substances at relatively low concentration are to be removed.

7. Factors Influencing Phase Equilibria

Several general factors influence phase equilibria and can be utilized in the logic of selecting processes and choosing mass separating agents. A generalized equilibration separation process may be regarded as having a source (feed) phase and a second, receiving phase. For the solute(s) of interest to move in the desired direction, the chemical potential of the solute in the receiving phase must be less than that in the source phase.

The partition coefficient K_i for a solute between two bulk phases is independent of solute concentration when ideal solutions exist in both phases or, in most instances, when the solute is very dilute in both phases. The partition coefficient is simply the ratio of the activity coefficient in the source phase to that in the receiving phase, if the activity coefficients and the partition coefficient are based upon the same concentration units (moles or mass per volume, weight fraction, etc.). If *preferential interactions* occur between solute and solvent [defined as the major component(s)] in either phase, the distribution of the component toward that phase will be enhanced. Similarly, if less affinity exists between solute and solvent molecules than between solvent molecules themselves, the solute will be driven toward the other phase.

The values of K_i for many phase-distribution processes are dominated by the *nonidealities* in one of the two phases. This is particularly true for processes that remove nonpolar or low-polarity solutes from aqueous solution in which the aqueous phase is highly nonideal (very large activity coefficients) and the receiving phase is much more nearly ideal. Thus relationships among many organic compounds based upon a single set of chemical parameters related to dispersion forces, polarity and polarizability, and acidity and basicity, serve to correlate such seemingly diverse partitioning properties as solubility in water [2], adsorption from water onto activated carbon [3], and extraction from water into 1-octanol [4]. All of these situations are dominated by aqueous-phase nonidealities.

Dimerization or polymerization of the solute, or formation of solute molecules into micelles in one of the phases, serves to increase the distribution (i.e., increase K_i) of the solute in that phase at higher solute concentrations.

Another common equilibrium feature is the *saturation* of a phase. In adsorption processes, the finite amount of solid surface area present provides an upper limit on the amount of solute that can be taken up within the capacity of the selective layer adjacent to the surface. The same is true of gas – liquid surface capacity in foam or bubble fractionation. In these cases, the partition coefficient toward the surface phase decreases as saturation is approached. This is another reason why surface-based separation processes are more useful when the solute to be removed is present in low concentration.

A similar situation exists where *chemical reactions* are involved (e.g., ion exchange, reversible chemical complexation). The reactant in the receiving phase has a limited capacity, in that the stoichiometry of the underlying reaction(s) cannot be exceeded. Thus, a solvent phase containing a reactive organic extractant of molecular mass 400 at 40 wt % in an organic diluent can at most take up 5 wt % of a solute of molecular mass 50, with which the extractant forms a 1:1 complex. Complexation of additional solute molecules with a reactant molecule engenders additional uptake.

8. Sources of Equilibrium Data

Many measurements of phase-equilibrium properties exist, but they are widely scattered in the literature. For a particular system, a search of *Chemical Abstracts* may be the most useful

approach. *Complications of data* are given in [5–8] for vapor – liquid equilibria; [9] for liquid–liquid equilibria; [10] and [11] for solubilities of gases and solids in liquids; [12] and [13] for bulk solid – liquid equilibria; and [14] for phase diagrams in general.

Methods for prediction, correlation, and interpretation of vapor–liquid and liquid – liquid phase equilibria are treated in [15] and summarized in [16]. Prominent among these is the UNIFAC method, described for vapor – liquid equilibria in [17] and for liquid – liquid equilibria, in a more general context, in [18] and [19]. This method is suitable for mixtures with moderate degrees of nonideality but cannot yet be extended to situations involving simultaneous strong, specific chemical interactions. For further information, see → Estimation of Physical Properties.

Symbols

A exchanger total heat-transfer area (primary plus secondary, if any) on one side, m^2 or ft^2

A_f fin or extended surface area on one side of the exchanger, m^2 or ft^2

A_{fr} frontal or face area of the exchanger, m^2 or ft^2

A_k total wall cross-sectional area for longitudinal conduction, m^2 or ft^2

A_o minimum free flow (or open) area, m^2 or ft^2

A_p primary surface area on one side of the exchanger, m^2 or ft^2

A_w total area for heat conduction from hot to cold fluid, m^2 or ft^2

B coefficient [Eq. (85)], dimensionless

b distance between two plates (fin height) in a plate-fin exchanger, m or ft

C flow stream heat capacity rate with a subscript c or h, $C = Wc_p$, W/K or Btu h^{-1} °F^{-1}

C^* heat capacity rate ratio $= C_{min}/C_{max}$, dimensionless

C_c flow-stream heat capacity rate of cold fluid $= (Wc_p)_c$, W/K or Btu h^{-1} °F^{-1}

C_h flow-stream heat capacity rate of hot fluid $= (Wc_p)_h$, W/K or Btu h^{-1} °F^{-1}

C_{max} maximum of C_c and $C_h = (W c_p)_{max}$, W/K or Btu h^{-1} °F^{-1}

C_{min} minimum of C_c and $C_h = (W c_p)_{min}$, W/K or Btu h^{-1} °F^{-1}

CHF critical heat flux

Co convection number [Eq. (127)], dimensionless

c constant, used in many equations with specific value at each place

c_p specific heat of fluid at constant pressure, J kg^{-1} K^{-1} or Btu lbm^{-1} °F^{-1}

D_e equivalent diameter, m or ft

D_h hydraulic diameter, m or ft

d_B tube bundle diameter $= D_i - \delta_{sb}$, where δ_{sb} is the shell-to-bundle diametral clearance, m or ft

d_e fin tip diameter of an individually finned tube, m or ft

d_i inside diameter of a circular tube, m or ft

d_o outside diameter of a circular tube, m or ft

F log-mean temperature difference correction factor, dimensionless

F_{fl} fluid dependent parameter, dimensionless

Fr Froude number $= G^2 g^{-1} d_i^{-1} \varrho_1^{-2}$, dimensionless

f Fanning friction factor $= \tau_w/(\varrho v^2/2 g_c)$, dimensionless

f' modified friction factor per tube row $= \Delta p/(4 N_r G^2/2 g_c \varrho)$, dimensionless

f_{app} apparent Fanning friction factor, defined in Table 8, dimensionless

G mass velocity based on minimum free flow area $= W/A_o$, kg m^{-2} s^{-1} or lbm h^{-1} ft^{-2}

Gr Grashof number, [Eq. (176)], dimensionless

g acceleration due to gravitation, m/s^2 or ft/s^2

g_c proportionality constant in Newton's second law of motion, $g_c = 1$ and is dimensionless in SI units, $g_c = 32.174$ lbm ft lbf^{-1} s^{-2}

(H1) thermal boundary condition referring to constant axial wall heat flux with constant peripheral wall temperature

(H2) thermal boundary condition referring to constant axial wall heat flux with constant peripheral wall heat flux

h heat-transfer coefficient, W m^{-2} K^{-1} or Btu h^{-1} ft^{-2} °F^{-1}

ID tube inside diameter, m or ft

i_{lg} latent heat of vaporization, J/kg or Btu/lbm

i'_{lg} $= i_{lg} + 3/8 c_{p,l} (T_{sat} - T_w)$, J/kg or Btu/lbm

J heat-transfer coefficient correction factors for shellside leakage and bypass flows, refer to specific definitions after Equation (144), dimensionless

j Colburn factor $= St\, Pr^{2/3}$, dimensionless

k thermal conductivity of the fluid if no subscript, W m^{-1} K^{-1} or Btu h^{-1} ft^{-1} °F^{-1}

k_f thermal conductivity of the fin material, W m^{-1} K^{-1} or Btu h^{-1} ft^{-2} °F^{-1}

k_w thermal conductivity of the wall material, W m^{-1} K^{-1} or Btu h^{-1} ft^{-1} °F^{-1}

L tube length or fluid flow (core) length on one side of the exchanger, m or ft

L_{hy} hydrodynamic entrance length, m or ft

LMTD log-mean temperature difference, °C

l_{ef} effective flow length between major boundary layer disturbances, distance between interruptions, m

l^*_{ef} $= l_{ef}/D_h Re\, Pr$

l_f fin height for individually finned tubes $= (d_e - d_o)/2$, m or ft

M molecular weight, M_v for vapor, M_m for mean gas phase, kg/kg mol or lbm/lbm mol

MTD mean temperature difference, °C

m fin parameter, defined in Table 4 for each fin geometry (m with this meaning used only in the fin analysis), m^{-1} or ft^{-1}

N number of passes

N_b number of baffles

N_f number of fins per unit length in a tube – fin exchanger, m^{-1} or ft^{-1}

N_p number of flow passage on one side in a plate – fin exchanger

N_r number of tube tows in the flow direction

N_t number of tubes

NTU number of heat-transfer units $= UA/C_{min}$, $NTU_1 = UA/C_1$, $NTU_2 = UA/C_2$, dimensionless

Nu Nusselt number $= h D_h/k$, dimensionless

n exponent, dimensionless

OD tube outside diameter, m or ft

P temperature effectiveness of the tube-side stream, defined in Table 5, dimensionless

$\tilde{P}$ fluid pumping power $= W \Delta p/\varrho$, W or hp

Pr Prandtl number $= \mu c_p/k$, dimensionless

p fluid static pressure, Pa or lbf/ft^2

p_v, p_g vapor and noncondensable gas partial pressure, Pa or lbf/ft^2

Δp fluid static pressure drop on one side of a heat exchanger core, Pa or lbf/ft^2

Δp_f frictional pressure drop in two-phase flow, Pa or lbf/ft^2

$\Delta p_{f,g}$ single-phase pressure drop considering gas (with its flow rate) in the two-phase mixture flowing alone in the tube across full cross-section, $\Delta p_{f,l}$ defined similarly for the liquid, Pa or lbf/ft^2

$\Delta p_{f,go}$ single-phase pressure drop considering total flow rate of two-phase mixture as gas flowing in the tube across full cross-section; $\Delta p_{f,lo}$ defined similarly for the liquid, Pa or lbf/ft^2

Δp_{hs} hydrostatic (graviational) pressure drop, Pa or lbf/ft^2

Δp_m momentum pressure drop, Pa or lbf/ft^2

p_r reduced pressure $= p/p_{cr}$, dimensionless

p_t tube pitch, center-to-center distance between tubes, m or ft

Q_T total heat removed from vapor to given point, W or Btu/h

q heat-transfer rate, heat duty, W or Btu/h

q'' heat flux, heat-transfer rate per unit area W/m^2 or Btu h^{-1} ft^{-2}

R heat capacity rate ratio, $R_1 = C_1/C_2$, $R_2 = C_2/C_1$, dimensionless

$\boldsymbol{R}$ thermal resistance based on area A, $R_0 = 1/UA$ (see text after Eq. (7) for the definitions of other thermal resistances, K/W or h °F/Btu)

R pressure drop correction factors for shell-side leakage and bypass flows, refer to specific definitions after Equation (148), dimensionless

Re Reynolds number based on the hydraulic diameter $= G D_h/\mu = \varrho v D_h/\mu$, dimensionless

Re_d Reynolds number based on the tube outside diameter $= G d_o/\mu = \varrho v d_o/\mu$, dimensionless

$Re_{\Gamma,L}, Re_{\Gamma,z}$ mean and local film Reynolds numbers, defined by Equations (112) and (104), dimensionless

St Stanton number $= h/(G c_p)$, dimensionless

s fin spacing or fin pitch $s = 1/N_f$; also transverse spacing for offset-strip fins, m or ft

s' distance between two fins $= s - \delta$, m or ft

1. Introduction

The topic heat exchange includes a broad range of topics that cannot be treated here. This article describes heat exchangers, and would be better entitled Heat Exchangers.

A heat exchanger is a device that transfers thermal energy between two or more fluids that have differing temperatures. Typical applications involve heating or cooling of a fluid stream, evaporation or condensation of single or multicomponent fluid stream, and heat recovery or rejection from a system. In other applications, the purpose is to heat, cool, condense, vaporize, sterilize, pasteurize, fractionate, distil, concentrate, crystallize, or control process fluid. In some heat exchangers, the fluids transferring heat are in direct contact. In other exchangers, heat transfer between fluids takes place through a separating wall or into and out of a wall in a transient manner. In most process heat exchangers, fluids are separated by a heat-transfer surface, and ideally they do not mix. Such exchangers are referred to as *direct transfer type* or simply *recuperators.* In contrast, exchangers in which there is an intermittent flow of heat from the hot to cold fluid–via heat storage and heat rejection through the exchanger surface or matrix–are referred to as *indirect transfer type or storage type exchangers,* or simply *regenerators.*

In this article, comprehensive information is presented for design of single-phase and two-phase heat exchangers used in process, power, petroleum, air-conditioning and refrigeration, cryogenics, transportation, and other industries. Also, design information is provided on impor-

tant operating problems such as flow-induced vibration, flow maldistribution, and fouling.

2. Classification of Heat Exchangers

Heat exchangers can be classified according to transfer process, construction, flow arrangement, surface compactness, number of fluids, and heat-transfer mechanisms as shown in Figure 1 [1]. They can also be classified according to the process function (Fig. 2), industry, type of fluid, and site of installation in the plant.

2.1. Classification According to Construction

2.1.1. Tubular Heat Exchangers

Tubular heat exchangers are generally built of circular tubes, although elliptical and rectangular tubes have also been used. There is considerable design flexibility because the core geometry can be varied easily by changing the tube diameter, length, and arrangement. Tubular exchangers can be designed for any operating temperatures, pressures, and any temperature and pressure differences between the fluids, limited only by the materials of construction. They can be designed for special operating conditions: heavy fouling, highly viscous flow, corrosiveness, toxicity, radioactivity, etc. These exchangers may be further classified as shell-and-tube, double-pipe, spiral and tube – coil exchangers. Only the first two types, the most important, are described further here.

2.1.1.1. Shell-and-Tube Exchangers

Shell-and-tube exchangers are composed of round tubes mounted in a cylindrical shell with the tube axis parallel to that of the shell. One fluid flows inside the tubes, the other flows across and along the tubes. The major components of this exchanger are tubes (or tube bundle), shell, stationary or front-end head, rear-end head, baffles, and tubesheets. Detailed components for several shell-and-tube exchangers are shown in Figure 3.

A variety of internal constructions are used in shell-and-tube exchangers, depending upon the desired heat-transfer and pressure-drop performance and the methods employed to reduce thermal stresses, to prevent leakages, to provide for ease of cleaning, to contain operating pressures and temperatures, and to control corrosion. These exchangers are classified and constructed according to Tubular Exchanger Manufacturers Association (TEMA) standards [2] in the United States or modified TEMA standards in other countries.

TEMA has developed a notation system to designate major types of shell-and-tube exchangers. In this system, each exchanger is designated by a three letter combination, the first letter indicating the front-end head type, the second the shell type, and the third the rear-end head type. These are identified in Figure 4. Some of the common shell-and-tube exchangers are AES, AEP, CFU, AKT, and AJW. Other special types of shell-and-tube exchangers have front-end and rear-end heads different from those in Figure 3. These exchangers may not be identifiable by the TEMA letter designation.

The sizes of shells or tube bundles are designated by describing the shell/tube bundle nominal diameter and tube lengths (both in inches, 1 in = 2.54 cm, by TEMA). Except for the kettle reboiler, the nominal diameter is the shell inside diameter, rounded off to the nearest integer; for the kettle reboiler, the nominal diameter is the port diameter (the shell inside diameter (*ID*) near the tube fluid inlet) followed by the shell *ID*. The three letter designation of the type of the exchanger follows the size of shell. Some examples of Figure 3 are the following:

B) Fixed tubesheet exchanger with bonnet stationary head, single pass on shellside and tubeside, 23-1/4 in (59.1 cm) shell inside diameter, 18 ft (5.49 m) tubes. Size 23 – 216 type BEM.
C) Outside packed floating head exchanger with removable channel and cover, one shell pass, two tube passes, shell inside diameter 21 in (53.3 cm) with 14 ft (4.27 m) tubes. Size 21 – 168 type AEP.
D) U-tube exchanger with stationary head channel integral with tubesheet and removable cover, two-pass shell with longitudinal baf-

Figure 1. Classification of heat exchangers

Figure 2. Classification according to process function

fle, 31 in (78.7 cm) shell inside diameter, 20 ft (6.1 m) tubes. Size 31 – 240 type CFU.

E) Pull-through floating head kettle-type reboiler with removable channel and cover, 25 in (63.5 cm) port diameter and 44 in (1.12 m) shell inside diameter with 20 ft (6.1 m) tubes. Size 25/44 – 240 type AKT.

TEMA has set up mechanical standards for design, fabrication, and materials for three classes of heat exchangers: R, C, and B. *Class R* designates the unfired shell-and-tube heat exchangers generally used for severe conditions in petroleum and related processing. *Class C* designates the unfired shell-and-tube heat exchangers generally used for moderate conditions of commercial and general processing. *Class B* designates the unfired shell-and-tube heat exchangers used for chemical process service. Generally, Class B exchangers employ nonferrous materials, while the other heat exchangers employ ferrous materials.

Further description of the individual components of shell-and-tube exchangers is provided in Section 4.2.

2.1.1.2. Double-Pipe Heat Exchangers

Double-pipe heat exchangers usually consist of concentric pipes. One fluid flows in the inner pipe and the other flows countercurrently in the annulus between the pipes. This is perhaps the simplest heat exchanger. Flow distribution is no problem, and cleaning is done easily by disassembly. This configuration is appropriate when one or both of the fluids are at very high pressure because containment in small diameter pipe or tubing is less costly than containment in large diameter shell. Double-pipe exchangers are generally used for the small capacity applications where the total heat-transfer surface area is 50 m^2 (500 ft^2) or less. Stacks of double-pipe or multitube-type heat exchangers are also used in some process applications with radial or longitudinal fins.

2.1.1.3. Drip-Type Heat Exchangers

Drip or trombone exchangers are serpentine or flattened helical coil tubes with water flowing over the horizontal tubes in a falling film. They are similar to double-pipe exchangers except that the outer pipe jacket is omitted. It has the advantages of a high water side heat-transfer coefficient, easy cleaning while in operation, and no possibility of leakage of water contaminating the process fluid. Additional cooling can take place by evaporation, but this is of minor importance. Major disadvantages are the large space requirement, the need for a sump pump or sewer line, and messy operation.

2.1.2. Plate-Type Heat Exchangers

Plate-type heat exchangers are usually built of thin plates (all prime surface), which are either smooth or corrugated and are either flat or wound in an exchanger. Generally, these exchangers cannot accommodate high pressure and temperature differences. These exchangers may be further classified as plate, spiral plate, lamella, and platecoil exchangers [1], the first two types being described further.

2.1.2.1. Plate Heat Exchangers

The plate and frame or gasketed plate heat exchanger (PHE) consists of a number of thin, rectangular metal plates sealed around the edges by gaskets and held together in a frame as shown in Figure 5. The frame usually has a fixed-end cover (headpiece) fitted with the connecting ports and a movable cover plate (pressure

plate, follower, or tailpiece). In the frame, the plates are suspended from an upper carrying bar and guided by a bottom carrying bar to ensure proper alignment. The plate pack with fixed and movable end covers is clamped together by lateral bolts. The carrying bars are longer than the compressed stack so that when the movable end cover is removed, plates may be slid along the support bars for inspection and cleaning.

Figure 5. A plate heat exchanger (courtesy of Alfa-Laval AB, Sweden)
a) Movable end cover; b) Fixed end cover; c) Plate pack; d) Carrying bar; e) Compression bolt

Each plate is made by stamping or embossing a corrugated (or wavy) surface pattern on sheet metal. Typical plate geometries (corrugated patterns) are shown in Figure 6. The plates are assembled with the corrugations on successive plates abutting so as to form narrow interrupted or torturous flow paths. Since adjacent plates are in mutual contact, the mean plate spacing is well defined and determined by the geometry of the corrugations. The corrugations also improve the rigidity of the plates and provide mechanical support to the plate pack through multiple contact points. They also enhance the heat-transfer rate and decrease fouling resistance by increasing the level of turbulence. Plates are designed as *hard* or *soft*, depending upon whether they generate high or low intensity of turbulence.

Sealing is accomplished by elastomeric gasket (typically 5 mm, 0.2 in, thick) that are fitted in special grooves provided along the edges of the plates and around the ports as indicated by the dark lines in Figure 6. Some manufacturers offer special interlocking types to prevent gasket blowout at high differential pressures. Typical gasket materials and their range of applications are listed in Table 1 [3].

A large number of pass arrangements are possible in a plate heat exchanger [3], [4] depending on the required heat-transfer duty, available pressure drops, minimum and maximum velocities allowed, and the flow rate ratio of the two fluid streams. Whether the plate exchanger is a single-pass or multipass unit, the thermodynamically superior counterflow or overall counterflow arrangement is used exclusively.

Some advantages of plate heat exchangers are as follows:

They can easily be taken apart for cleaning, inspection, and maintenance. The heat-transfer surface area can be readily changed or rearranged for a different task or anticipated changing loads, through the flexibility of plate size, corrugation patterns, and pass arrangements. The high turbulence due to plates reduces fouling to ca. 10 – 25 % that of a shell-and-tube exchanger. Because of the high heat-transfer coefficients, reduced fouling, absence of bypass and leakage streams, and pure counterflow arrangements, the surface area required for a plate exchanger is one-half to one-third that of a shell-and-tube exchanger for a given heat duty, thus reducing the cost, overall volume, and maintenance space for the exchanger. The gross weight of a plate exchanger is about one-sixth that of an equivalent shell-and-tube exchanger. Leakage from one fluid to the other cannot take place unless a plate develops a hole. Since the gasket is between the plates, any leakage from the gaskets is to the outside of the exchanger. The residence time for fluid particles on a given side is approximately the same. This is desirable for uniformity of heat treatment in application such as sterilizing, pasteurizing, and cooking. There are no significant hot or cold spots in the exchanger that could lead to the deterioration of heat-sensitive fluids. The volume of fluid held up in the exchanger is small; this is important with expensive fluids, for faster transient response, and for a better process control. Finally, high thermal performance can be achieved in plate exchangers. The high degree of counterflow makes temperature approaches of 1 °C possible. The high thermal effectiveness (up to ca. 93 %) facilitates economical low-grade heat recovery. Flow-induced vibration, noise, thermal stresses, and entry im-

Table 1. Gasket materials used in plate heat exchangers [3]

Gasket material	Generic name	Maximum operating temperature, °C	Applications	Comments
Natural rubber	*cis*-1,4-polyisoprene	70	oxygenated solvents, acids, alcohols	
SBR (Styrene butadiene)		80	general purpose aqueous, alkalies, acids, and oxygenated solvents	poor fat resistance
Neoprene	*trans*-1,4-polychloroprene	70	alcohols, alkalies, acids, aliphatic hydrocarbon solvents	
Nitrile		100 – 140	dairy products, fruit juices, beverages, pharmaceutical and biochemical applications; oil, gasoline, animal and vegetable oils, alkalies, and aliphatic organic solvents	resistant to fatty materials; particularly suitable for cream
Butyl (resin cured)		120 – 150	alkalies, acids, animal and vegetable oils, aldehydes, ketones, phenols, and some esters	poor fat resistance; suitable for UHT milk duties; resists inorganic chemical solutions up to 150 °C
Ethylene propylene (EPDM) rubber		140	alkalies, oxygenated solvents	unsuitable for fatty liquids
Silicone rubber	polydimethylsiloxane	140	general low temperature use, alcohols, sodium hypochlorite	
Fluorinated rubber		175	high temperature aqueous solutions, mineral oils and gasoline, organic solvents, animal and vegetable oils	
Compressed asbestos fiber		200 – 260	organic solvents, high operating temperature applications	

pingement problems of shell-and-tube exchangers do not exist in plate heat exchangers.

Some inherent limitations of plate heat exchangers are caused by the plates and gaskets:

The plate exchanger can be used for a maximum pressure of about 2.5 MPa (360 psig), but usually below 1.0 MPa (150 psig). The gasket materials (except for the Teflon-coated type) restrict the use of plate exchangers in highly corrosive applications; they also limit the maximum operating temperature to 260 °C (500 °F), although operation is usually carried out below 150 °C (300 °F) to avoid the use of expensive gasket materials. For equivalent flow velocities, the pressure drop in plate exchangers is very high compared to shell-and-tube exchangers. However, the flow velocities are usually low and the plate lengths are short, so the resulting pressure drops are generally acceptable. Because of the long gasket periphery, plate exchangers are not suitable for high vacuum applications. Plate exchangers are not suitable for erosive duties [5]

or for fluids containing fibrous materials. In certain cases, suspensions can be handled, but to avoid clogging, the largest suspended particles should be at most one-third the size of the average channel gap. Viscous fluids can be handled, but extremely viscous fluids lead to flow maldistribution problems, especially on cooling. Plate exchangers should not be used for toxic fluids due to potential gasket leakage. Some of the largest units have a total surface area of about 2500 m^2 (27 000 ft^2) per frame. Large differences in fluid flow rates of two streams with reasonable pressure drops cannot be handled in a plate exchanger.

2.1.2.2. Spiral-Plate Heat Exchangers

The spiral-plate heat exchanger consists of two relatively long strips of sheet metal, provided with welded studs for plate spacing, and wrapped helically around a split mandrel to form a pair of spiral channels for two fluids, as shown in Figure 7. Thus, each fluid has a long single passage arranged in a compact package. The basic spiral element is sealed by either welding at each side of the channel or by providing a gasket (asbestos-based) at each end cover to obtain the following arrangements of the two fluids: (1) both fluids in spiral counterflow; (2) one fluid in spiral flow, the other in crossflow across the spiral; or (3) one fluid in spiral flow, and the other in a combination of crossflow and spiral flow. The whole assembly is housed in a cylindrical shell enclosed by two circular end covers, either flat or conical.

Figure 7. A spiral plate heat exchanger with both fluids in spiral counterflow

The spiral plate exchanger has a relatively large diameter because of the spiral turns. This is a noncompact heat exchanger with a maximum of about 185 m^2 (2000 ft^2) surface area for a maximum 1.47 m (58 in) diameter shell. The heat-transfer coefficients are not as high as in a plate exchanger if the plates are not corrugated. However, the heat-transfer coefficient is higher than that for a shell-and-tube exchanger because of curved rectangular passages. Hence, the surface area requirement is about 20 % lower than a shell-and-tube unit for the same heat duty.

The advantages of the spiral-plate heat exchanger are the following:

It can handle viscous, fouling liquids, and slurries more readily because of the *single passage*. The fouling rate is low compared to the shell-and-tube unit. It is more amenable to chemical, flush, and reversing fluids cleaning techniques, and thus maintenance is low compared to a shell-and-tube unit. The internal void volume is low compared to a shell-and-tube exchanger, and it is well suited as a condenser or reboiler.

The disadvantages of this exchanger are the following:

The maximum size is limited. The maximum operating pressure is limited to 1000 kPa (150 psig) for large units and the maximum operating temperature is limited to 500 °C (930 °F) with compressed asbestos gaskets. Field repair is difficult due to construction features.

2.1.3. Extended-Surface Heat Exchangers

The tubular and plate-type exchangers described previously are all prime surface heat exchangers, except for those having low finned circular tubes. The design thermal effectiveness is usually ≤ 60 % for a single-shell unit. The heat-transfer surface area density is usually $\leq 700\ m^2/m^3$ (200 ft^2/ft^3). In many applications, a much higher exchanger effectiveness (up to 98 %) is essential, and the box volume and mass are limited so that a more compact surface is mandated. When either a gas or a liquid having a low heat-transfer coefficient is the fluid on one or both sides, it results in a large heat-transfer surface area requirement. This is met by adding fins on the primary surface on one or both fluid sides. Plate – fin and tube – fin geometries are the

two most common types of extended surface exchangers.

2.1.3.1. Plate – Fin Heat Exchangers

Plate – fin heat exchangers have fins or spacers sandwiched between parallel plates (referred to as plates or parting sheets) as shown in Figure 8. Sometimes fins are incorporated in a flat tube with rounded corners (referred to as a formed tube), thus eliminating a need for the side bars. Other plate – fin constructions include drawn-cup or tube-and-center configurations. These are shown in Figure 9. The plates or flat tubes separate the two fluid streams and the fins form the individual flow passages. Alternate fluid passages are connected in parallel by suitable headers to form the two or more sides of the exchanger. Fins are die- or roll-formed and are attached to the plates by brazing, soldering, adhesive bonding, welding, mechanical fit, or extrusion. Fins are used on both sides in gas-to-gas heat exchangers. In gas-to-liquid applications, fins are usually used only on the gas side–if employed on the liquid side, they are used primarily for structural strength and flow mixing purposes. Fins are also sometimes used for pressure containment and rigidity. In Europe, the plate – fin exchanger is referred to as the *matrix heat exchanger*.

Figure 8. Basic components of a plate-fin heat exchanger
a) Plate or parting sheet; b) Fin; c) Side bar

Plate fins are categorized as (1) plain (i.e., uncut) and straight fins, such as plain triangular and rectangular fins, (2) plain but wavy fins, and (3) interrupted fins such as offset strip, louver, perforated, and pin fins. Examples of commonly used fins are shown in Figure 10. The velocity and temperature boundary layer thicken along the flow length on plain surfaces resulting in both a lower heat-transfer coefficient and a lower friction factor compared to interrupted fins. Plain fins are used when the pressure drop is critical, and interrupted or wavy fins cannot meet the pressure drop requirement together with a flow (or frontal) area constraint. For wavy fins, the boundary layers are either thinned or interrupted when the fluid follows waves, resulting in both a higher heat-transfer coefficient and a higher friction factor. Boundary layers can be disrupted further if the fin surface is made highly discontinuous. Examples are strip fins, louver fins, and perforated fins. Strip fins are also referred to as offset fins, lance-offset fins, serrated fins, and segmented fins. Many variations of interrupted fins are used in industry since they are more efficient than plain fins, and are therefore used when allowed by the design constraints.

Plate – fin exchangers are generally designed for moderate pressures (< 700 kPa (100 psig)), although plate – fin exchangers for operating pressures up to ca. 8300 kPa (1200 psig) are available commercially. The temperature limitation depends on the method of bonding and the material employed. Such exchangers have been used for temperatures up to ca. 840 °C (1550 °F). Plates and fins are made from a variety of materials.

Plate – fin exchangers have been built with a surface area density of up to 5900 m^2/m^3 (1800 ft^2/ft^3). There is total freedom in selecting the fin surface areas on each fluid side, as required by the design, by varying fin height and fin density. Although typically fin densities are 120 – 700 fins/m (3 – 18 fins/in), applications exist for as many as 2100 fins/m (53 fins/in). Common fin thicknesses range from 0.05 to 0.25 mm (0.002 – 0.01 in). Fin heights may range from 2 to 25 mm (0.08 – 1.0 in). A plate – fin exchanger with 600 fins/m (15.2 fins/in) provides about 1300 m^2 of heat-transfer surface area per cubic meter volume occupied by the fins (400 ft^2/ft^3). Plate – fin exchangers are manufactured in virtually all shapes and sizes.

Plate – fin exchangers are widely used in electric power plants (gas turbine, steam, nuclear, fuel cell, etc.), in thermodynamic cycles (heat pump, refrigeration, etc.), and in electronics, cryogenics, gas-liquefaction, air-conditioning, transportation, and waste-heat-recovery systems.

2.1.3.2. Tube – Fin Heat Exchangers

Tube – fin heat exchangers may be classified as conventional and specialized tube – fin exchangers. In a conventional tube – fin exchanger, heat transfer between the two fluids takes place through the tube wall by conduction. However, in a heat-pipe exchanger, a specialized type of tube – fin exchanger, tubes with both ends closed act as a separating wall, and heat transfer between the two fluids takes place through this separating wall (heat pipe) by conduction, and evaporation and condensation of the heat-pipe fluid [6].

In the gas-to-liquid exchanger, the heat-transfer coefficient on the liquid side is generally very high compared to that on the gas side. Hence, to have balanced thermal conductances (approximately equal hA) on both sides for an optimum heat exchanger, fins are used on the gas side to increase surface area A. This is also true with a condensing or evaporating fluid stream on one side and gas on the other. In addition, if the pressure is high for one fluid, it is generally economical to employ tubes.

In a tube – fin exchanger, round and rectangular tubes are the most common, although elliptical tubes are also used. Fins are generally used on the outside but in some applications they may be used on the inside of the tubes. They are attached to the tubes by a tight mechanical fit, tension winding, adhesive bonding, soldering, brazing, welding, or extrusion.

Fins on the outside of the tubes may be categorized as follows:

1) Normal fins on individual tubes, referred to as individually finned tubes or simply as finned tubes, as shown in Figure 11
2) Continuous (plain, wavy, or interrupted) flat fins on an array of tubes, as shown in Figure 12
3) Longitudinal fins on individual tubes as shown in Figure 13

The exchanger with continuous flat fins is usually less expensive on a unit heat-transfer surface area basis because of its simple and mass production type construction features. Individually finned tubes are more rugged and practical in large tube – fin exchangers. Longitudinal fins are generally used in condensing applications, and for viscous fluids in double pipe exchangers.

Figure 11. Individually finned tubes

Figure 12. Flat fins on an array of tubes

Shell-and-tube exchangers sometimes employ low finned tubes to increase the surface area on the shellside when the shellside heat-transfer coefficient is low compared to the tubeside coefficient, such as with highly viscous liquids, gases, or condensing refrigerant vapors. The low finned tubes are generally helical or annular fins on individual tubes. Longitudinal fins on indi-

Figure 13. Longitudinal fins on individual tubes (courtesy of Brown Fintube Co., Tulsa, Oklahoma)
A) Continuous plain; B) Cut and twisted; C) Perforated; D) Internal and external longitudinal fins

vidual tubes are also used in shell-and-tube exchangers. Fins on the inside of the tubes are of two types: integral fins as in internally finned tubes, and attached fins.

Tube – fin exchangers can withstand high pressures on the tube side. The highest temperature is again limited by the type of bonding, materials employed, and material thickness. Tube – fin exchangers usually have lower compactness compared to the plate – fin units.

Tube – fin exchangers with an area density of about 3300 m^2/m^3 (1000 ft^2/ft^3) have been built. On the fin side, the desired surface area can be employed by using the proper fin density and fin geometry. The typical fin densities for continuous flat fins vary from 250 to 800 fins/m (6 – 20 fins/in), fin thicknesses vary from 0.09 to 0.25 mm (0.0035 – 0.010 in), and fin flow lengths from 25 to 250 mm (1 – 10 in). A tube – fin exchanger having continuous flat fins with 400 fins/m (10 fins/in) has a surface area density of ca. 720 m^2/m^3 (220 ft^2/ft^3).

Tube – fin exchangers are employed when one fluid stream is at a higher pressure or has a significantly higher heat-transfer coefficient compared to the other fluid stream. As a result, these exchangers are extensively used as condensers and evaporators in air-conditioning and refrigeration applications, as condensers in electric power plants, as oil coolers in propulsive power plants, and as air-cooled exchangers (see fin – fan exchangers, Section 9.1.2.3) in process and power industries.

2.1.4. Regenerators

The regenerator is a storage-type exchanger. In order to have continuous operation, either the matrix must be moved periodically into and out of the fixed streams of gases, as in a *rotary regenerator* (Fig. 14A), or the gas flows must be diverted through valves to and from the fixed matrices as in a *fixed-matrix regenerator* (Fig. 14B). The latter is also sometimes referred to as a *periodic-flow regenerator* or a *reversible heat accumulator.*

A) Rotary type; B) Valved type
a) Matrix; b) Valve positions

The rotary regenerator is usually a disk type in which the matrix (heat-transfer surface) is in a disk form and fluid flows axially. It is rotated by a hub shaft or a peripheral ring gear drive. Disk-type rotary regenerators are variously referred to as heat wheel, thermal wheel, Munter wheel, or Ljungstrom wheel, depending on their application. When the gas flow is laminar, the disk-type rotary regenerator is also referred to as a laminar flow wheel.

The thermodynamically superior counterflow arrangement is usually employed for storage-type heat exchangers. For some applications, a parallel flow arrangement may be used, but there is no counterpart of the singlepass or multipass crossflow arrangements common in recuperators. For a rotary regenerator, the design of seals to prevent leakages of hot to cold fluids and *vice versa* becomes a difficult task, especially if the two fluids are at significantly differing pressures. Rotating drives also pose a challenging mechanical design problem.

Major advantages of the regenerators are the following:

A much more compact surface may be employed compared to a recuperator. Most fin configurations of plate – fin exchangers, and any finely divided matrix material (high specific heat preferred) may be used providing they achieve high surface area density. Regenerators have been made from metals, ceramics, nylon, plastics, and paper, depending upon the applications. The cost of the regenerator surface per unit of transfer area is usually substantially lower than that for the equivalent recuperator. Compact regenerators usually have a smaller volume and are low in weight compared to an equivalent recuperator. The matrix surface has self-cleaning characteristics for low gas-side fouling because the hot and cold gases flow in alternatively opposite directions in the same fluid passage. Compact surface area density and the counterflow arrangement make the regenerator ideally suited for gas-to-gas heat exchanger applications requiring high exchanger effectiveness, generally exceeding 85 %.

A major disadvantage of the regenerator is an unavoidable carryover of a small fraction of the fluid trapped in the passage to the other fluid stream just after the periodic flow switching. Where fluid contamination is prohibited, a regenerator cannot be used. Hence, the regenerators are used exclusively for gas-to-gas heat or energy transfer.

2.2. Classification According to Process Function

The major process functions for industrial heat exchangers are heating, cooling, chilling, condensation (total or partial), evaporation and boiling, and waste heat recovery or heat rejection. Single-phase heating and cooling applications are relatively simple to design and understand, and are discussed in Section 8. More important but more difficult applications are the design of condensers and liquid-to-vapor phase exchangers (evaporators, boilers, etc.) because of the presence of two-phase phenomena as well as many different industrial uses. These exchangers are further classified next.

2.2.1. Condensers

Condensers are widely used in power generation, chemical process, air-conditioning, automotive, and many other industries. They are classified in Figure 15 (modified from [7]). Broadly speaking, they are either direct contact type or indirect contact type (stream separated).

In a direct contact condenser, the condensing process stream and coolant come into direct contact with each other and heat is transferred. These condensers are inexpensive, have high heat-transfer rates per unit volume, and fouling is not a problem. However, applications are limited due to mixing of the process stream with the coolant. In a pool condenser, the condensing vapor is injected into the pool of liquid coolant. The spray condenser is the most common direct contact condenser in which subcooled liquid is sprayed into the vapor as shown in Figure 16A. If the coolant is dirty, the spray nozzle would clog; in this case a tray condenser as shown in Figure 16B can be used.

Condensers in which the two fluid streams are separated by a wall are classified according to major exchanger construction types as shown in Figure 15. The most common type of condenser used in the power and process industry is the shell-and-tube exchanger. The coolant can be either water (or liquid) or a colder process

Figure 15. Classification of condensers

stream which requires heating. In power plants, the condenser is used to condense the turbine exhaust steam or preheat the feedwater with condensing steam bled from the turbine. The turbine exhaust steam condenser is referred to as the *surface condenser* or *vacuum condenser.* It has circular tubes and is usually very large; a circular shell is used when heat-transfer surface area is less than about 4650 m^2 (50 000 ft^2), otherwise a rectangular shell is used. The steam is condensed on the shellside. Good venting of noncondensables (to maintain high heat-transfer coefficients) and very low pressure drops on the steam side are the most important design criteria for surface condensers. Further construction details and thermal design are presented in [8].

In a feedwater heater, the boiler feedwater in tubes is heated with a superheated steam on the shell side. On the steam side, one or more of the three modes (desuperheating, condensing, and subcooling) may take place in the feedwater heater, and two- or three-zone feedwater requires special design features on the shellside of a shell-and-tube exchanger. The feedwater heater is usually a two-pass (U tube) exchanger mounted horizontally (Fig. 17), vertically channel-down, or vertically channel-up. Construction details, thermal performance relationships, and operating problems are dealt with in [9].

Figure 16. A) Spray condenser; B) Tray condenser

In the process industry, condensation occurs either inside or outside the tubes, the tubes being either horizontal or vertical, and the condensate may be a single component or multicomponent (miscible and/or immiscible) pure vapor with or without noncondensable gases. Condensation may be total (as with a pure vapor) or partial (single or multicomponent vapors with or without noncondensables). In addition to condensation, desuperheating and/or subcooling may also take place in a condenser. One of the most important design features of a condenser is to provide a vent for the removal of noncondensable gases

Table 2. Guide to the selection of type of shell-and-tube condenser [7]

Type	For subcooled condensate	For mixed vapors and/or noncondensables	Pressure range (for pressures between 4 kPa and 10^3 kPa, all types are satisfactory) ∗		If fouling or polymerization	For corrosive condensates or vapors
			below 4 kPa	above 10^3 kPa		
Inside tubes						
Vertical upflow (with reflux condensate)	not applicable	limited to small quantity of low boiler	very poor	good	not applicable	fair
Vertical downflow	good	excellent	poor	excellent	fair	good
Horizontal	very poor but possible with separate subcooling pass	good in annular flow, poor in stratified flow	poor	excellent	fair	good
Outside tubes						
Vertical	possible but not recommended	good	fair	poor–high shell cost	very poor	poor–alloy shell required
Horizontal	not recommended since predictions of cooling coefficient and effective area is unreliable	poor for wide condensing mixtures; good with noncondensables if baffle space is varied; heat and mass transfer prediction is unreliable	fair	poor–high shell cost	very poor	poor

∗ (0.04 – 10 bar)

(regardless of how small they may be in the vapor). The vent should be located near the coldest part of the condenser to avoid escape of vapor, but should be high enough so that it does not flood with condensate. An impingement plate should be placed under the vapor inlet nozzle to prevent tube erosion and possible flow-induced vibrations. A variety of shell types have been used depending upon the applications such as E (single- or multi-segmental baffles), G, H, J, and X, the X shell having the lowest pressure drop on the shell side. Table 2 provides guidelines for the selection of shell-and-tube condensers; further details are available in [7]. Two special types of total condensers, whereby all of the vapor is condensed in the condenser, used in specific applications are a total (with subcooling) condenser and a reflux or knockback condenser shown in Figure 18. These condensers are employed when the liquid in the reactor must be kept at boiling point, or when volatile liquid is stored in a tank (connected to the condenser). These condensers differ according to where the vapor enters the condenser, either at the top or bottom; if vapor entry is at the top, subcooling in the condenser is possible, and if entry is at the bottom, subcooling is not possible. The reflux

Figure 18. A) Total condenser; B) Reflux or knockback condenser
a) Reactor

condenser returns a hot condensate with most of the low boiling components stripped out.

Extended surface condensers are either tube – fin or plate – fin type and generally have air as the coolant. Tube – fin condensers are used in power and process industries, and in air-conditioning applications. Plate – fin condensers are used in the cryogenics industry.

Air-cooled condensers used in the process industry have a horizontal individually-finned tube bundle, and condensation takes place inside the tubes, air being blown across the tubes on the outside. The condenser usually has a large surface area and short air flow length in order to minimize the fan power consumption. The air is circulated either by forced or induced draft over the tubes. Further details are presented in [10]. Air-cooled condensers used in air-conditioning industry have flat fins (with waves or louvers for enhancement) on round tubes. They are usually smaller than those used in the process industry.

Plate – fin exchangers (see Fig. 8) are used in the cryogenics industry, where on one side condensation takes place (e.g., of air) and on the other side boiling or evaporation take place (e.g., of liquid nitrogen). These condensers are highly efficient (approach temperatures of 1 – 5 °C), compact, and of brazed aluminum construction. Flow passages are small, hence the fluids need to be clean or non-foulant. Heat-transfer and flow friction correlations and general design theory are dealt with in [11].

2.2.2. Liquid-to-Vapor Phase-Change Exchangers

Heat exchangers that involve a phase change from liquid to vapor on one side of a two-fluid exchanger are broadly classified as boilers and vaporizing exchangers, as shown in Figure 19. Boilers are fired exchangers in which fuel is burned to heat the air, which in turn vaporizes the fluid on the other side. Vaporizing exchangers are unfired; in most cases (except for steam generators), condensing steam is used to vaporize the fluid on the other side. The unfired vaporizing exchangers can be classified further– as steam generators, waste heat boilers, evaporators, reboilers, and vaporizers. *Steam generators* are used to generate saturated or superheated steam in power plants. Construction details and design theory of nuclear plant steam generators are covered in [12], [13]. *Waste heat boilers* are used to recover waste heat from a

variety of chemical processes. If the evaporation of water or an aqueous solution takes place in a vaporizing exchanger, it is referred to as an *evaporator.* A vaporizing exchanger (which supplies the heat required to generate vapors in a distillation process) located at the bottom of a distillating column is referred to as a *reboiler* regardless of whether or not the vapor generated is steam. A vaporizing exchanger is referred to as a *vaporizer* when it is neither used to generate the steam nor is it part of a distillation process. An evaporator is designated a *chemical evaporator* when it is used to concentrate a chemical solution by evaporation of part of the solvent. When it is used for the production of pure water or for any of the evaporative processes associated with power generation, it is referred to as a *power-plant evaporator.*

Because of their importance in the process industry, evaporators, reboilers, and waste heat boilers are dealt with in more detail.

2.2.2.1. Chemical Evaporators

Chemical evaporators are common in many industries such as the chemical, paper and pulp, pharmaceutical, food, dairy product, fruit juice, and beverage industries. The final product is either concentrate, crystal, or powder. They can be classified further according to the type of construction and means of energy supply, as shown in Figure 20A and B.

Classification According to Construction. *Shell-and-tube-evaporators* are the most commonly used chemical evaporators. In vertical orientation, the exchanger is singlepass and usually has support plates on the shellside. Steam is generally used on the shellside, while the feed which needs to be concentrated flows through the tubeside. This is because the tubeside can readily meet the cleaning requirements. Horizontal shell-and-tube exchangers are either singlepass or two tube-pass units. A U-tube bundle is the most common type of bundle. To ensure no contamination from the shellside, a double tubesheet design is used.

The shell-and-tube construction for evaporators is the most versatile. They are used for high evaporation duties, with very viscous liquids, for crystallizing feeds, and for liquids containing large suspended particles. The major disadvantages of these evaporators are that the liquids have a relatively large residence time and high liquid holdup, which may be undesirable for rapid startup and shutdown with minimum wastage.

The recirculation in the evaporator may be natural or forced. In natural circulation, the flow is induced due to the density difference between the entering liquid and the evaporating liquid. In forced circulation, the liquid is circulated by a pump. Natural circulation evaporators are used for simpler evaporation requirements. Forced circulation evaporators are used for viscous and scaling liquids.

Natural circulation evaporators are used with low viscosity and low fouling liquids. The liquid circulation is maintained by the density difference between the hot and cold liquids; a pump is not used for liquid circulation, hence control of the circulation rate is not easy. Generally, a high headroom is needed to obtain the required circulation rate. Five types of natural circulation evaporators are commonly used: short-tube vertical, basket, long-tube vertical, rising film, and falling film type. For further details → Evaporation or [14–16].

Forced circulation evaporators are used when concentration is needed for thermally degradable, heavy fouling, viscous liquids, or when crystallization is required. For these applications, the temperature rise across the exchangers in one cycle is kept 2 – 3 °C (3 – 5 °F) or lower, which results in circulation rates 200 – 300 times greater than the evaporation rate. Fouling tendency is lower due to high velocities in the tube. However, pumping power is required for forced circulation. The cost of a forced circulation evaporator is generally higher than that of a natural circulation evaporator. The overall space requirement could be significantly reduced compared to a natural circulation evaporator for a given duty because of higher heat-transfer coefficients with forced circulation. By circulating the liquid with a pump, the flow rate is controlled independently of the heat transfer in the evaporator (evaporation rate), and as a result, the desired flow control could be achieved. Many types of forced circulation evaporators are in use. The most common ones are the submerged-tube type with either a vertical or horizontal tube bundle (heating element) totally submerged in

Figure 19. Classification of liquid-to-vapor phase-change exchangers

Figure 20. Classifiction of chemical evaporators

the liquid. For further details → Evaporation and [14], [15].

Plate evaporators (or plate and frame evaporators) are used when low to medium heat conditions are required. Four types of plate evaporators are available: falling film, rising/falling film, flash, and free-flow evaporators as described in [17].

The major advantages of plate evaporators are as follows: liquids have a low residence time as required for heat-sensitive liquids in pharmaceutical, fruit, and dairy products. Also, there is a low liquid holdup, which results in rapid startups and shutdowns with minimum wastage. They are relatively easy and fast to clean. Capacity can be increased or decreased by changing the number of plates.

The major disadvantage is that they cannot be used with very viscous liquids. Except for the flash evaporator, they are not suitable for liquids containing large suspended particles, or where crystallization may occur due to evaporation.

Agitated film-type evaporators, also referred to as wiped film or scraped film evaporators (see Fig. 21) are used when shell-and-tube or plate evaporators cannot be used. Some specific applications are: very viscous liquids, liquids with suspended particles, liquids with heavy scaling or foaming characteristics, and heat-sensitive liquids requiring a low residence time or high vacuums to reduce evaporation temperature.

Figure 21. Wiped film evaporators
a) Rotor assembly; b) Vaporizing section; c) Condenser

Basically, this evaporator consists of a vertical cylindrical jacketed vessel which is heated primarily by steam (sometimes by oil), a rotor with blades, and a drive system to rotate the blades. A horizontal tapered cylindrical evaporator is used for special applications. The clearance between the vessel and rotor blade is either fixed (as in cylindrical units) or adjustable (as in tapered units). During operation, the liquid is fed from the top, and is transported down in a helical path by the action of the blade rotation and gravity. Evaporation of the solvent takes place in the thin film formed at the wall. The thin film yields high heat-transfer coefficients that are not possible with other types of evaporators. Agitated film evaporators are designed for operating pressures ranging from vacuums to 1 MPa (150 psig), operating temperatures up to 340 °C (650 °F), surface area up to 40 m^2 (430 ft^2), and liquid viscosities up to 50 Pa s (50×10^3 cp, although special units up to 1000 Pa s (1×10^6 cp) are available. Since the heat-transfer surface area is small, the heating medium is generally at a high temperature to obtain reasonable evaporation rates.

The major benefits are: extremely low residence time (in seconds), wide product viscosity range (outlet : inlet viscosity ratio = 1000 or higher), minimum fouling of heat-transfer surface due to wiping action, high recovery rates due to "squeezing" of residues, and minimum back-mixing.

Some of the major applications are: concentration of food products (dairy concentrates, fruit juices, tomato pastes, etc.), heat sensitive tobacco products, re-refining of waste lube oil, and recovery of wash solvents in paint and varnish manufacture.

The capital cost of the agitated film evaporator is high. Also the moving parts, blades, and rotor need periodic maintenance.

Batch pan is one of the oldest methods of concentration. A spherical or a spherical cylindrical vessel is either jacketed or has internal coils for heat transfer. Because of heat transfer by natural convection in the vessel, the heat-transfer coefficient is generally low; the surface area is also limited. Hence, the batch pan has limited evaporation capacity. The residence time of the product is generally large, in hours. Hence, for heat sensitive liquids, the batch must be either operated at low temperatures or in vacuum.

Batch pans are now used only in limited applications, such as for the concentration of jams and jellies that contain whole fruits, in the pharmaceutical industry, and in fermentation processes.

Classification According to How Energy is Supplied. Steam is generally used as the heating medium in the evaporator. The cost of steam or energy requirement of an evaporator may be significant depending upon the application. If the vapor produced in the evaporation process or the hot concentrated liquid could be used to evaporate the liquid to be concentrated, the amount of steam required could be significantly reduced, resulting in a considerable saving in the operating cost.

Steam economy is defined as unit mass of solvent evaporated per unit mass of steam used. The steam economy of the evaporator can be increased significantly in a number of ways. The most common method is the use of multiple evaporators arranged in series or alternatively; these are referred to as multiple effect evaporators. The vapor evolved from one stage of evaporation is thus used as the heating medium in the subsequent stage where boiling is carried out at reduced pressure. An alternative method of increasing steam economy requires that the steam generated in the first stage be recompressed to a sufficient pressure so that it could be used as the heating medium in the stage in which it is generated. The steam can be recompressed either by thermocompression or by mechanical compression. For further details → Evaporation or [14–16], [18].

2.2.2.2. Reboilers

A reboiler is a heat exchanger used to generate vapors (aqueous or nonaqueous) from a process liquid at the base of a distillation column. The vapors generated are used to provide the energy for vaporization in the distillation column. All reboilers considered here have a flow boiling process for the vaporizing fluid. As shown in Figure 22, they are classified according to how this flow is induced, whether by natural circulation or by forced circulation. *Natural circulation* can occur due to the hydrostatic pressure difference created by the difference in density between the liquid in the downcomer at the bottom of the distillation column and the two-phase mixture from the reboiler leading to the distillation column. *Forced circulation* is achieved by a pump in the downcomer line, and is used where the hydrostatic pressure difference is not adequate for the required circulation in a natural circulation reboiler.

Natural Circulation (Thermosiphon) Reboiler. In a *kettle reboiler,* the vapor at the exit of the boiling liquid side is dry or almost dry; in other thermosiphon reboilers, it is a two-phase (vapor – liquid) mixture. Proper design of the inlet and outlet piping to the reboiler is essential to maintain minimum pressure drop in the piping.

The kettle reboiler (TEMA K shell), as shown in Figure 23A, usually consists of horizontal bundle of heated U tubes (two tubepasses), circular in cross section, placed in an oversized shell; a multiple tube-pass floating head bundle may also be used. The tube bundle diameter ranges from 50 to 70 % of the shell diameter. The liquid to be vaporized enters from below and covers the tube bundle; the vapor occupies the upper space in the shell without the tubes. The large empty space in the shell acts as a vapor disengaging space, and almost dry vapor exits from the top nozzle. Depending upon the length of the kettle and a need to reduce liquid entrainment, one or more vapor nozzles are used. The liquid is fed at a rate greater than the vaporization rate so that low volatile components do not build up in the shell. The small holdup space beyond the weir is used to control the removal of excess liquid (which includes nonvolatiles); the nozzle in this space is used to drain the excess liquid. Typical weir heights exceed bundle heights by 50 – 150 mm (2 – 6 in). To maintain a high liquid circulation rate, the tube pitch-to-diameter ratio is kept between 1.5 and 2. Generally, the kettle reboiler is considered as a pool boiling device, however flow boiling prevails in the tube bundle.

The *internal* or *tube-in-column reboiler,* as shown in Figure 23B, is similar to the kettle reboiler without the shell, and is directly inserted into the bottoms reservoir of the distillation column. It is used for low heat duties and nonfouling liquids, thus eliminating the need for a shell and piping.

The *vertical thermosiphon reboiler,* as shown in Figure 23C, has a TEMA E shell with single-

pass tubes in which boiling occurs. The tube diameter ranges from 25 to 50 mm (1 – 2 in) for low pressure operation with wide-boiling mixtures, and tube lengths are usually 2.4 – 3.7 m (8 – 12 ft). The outlet pipe is kept short with its flow area equal to the flow area of all tubes because of the high exit velocity. The inlet pipe area is kept small (up to 50 % of the tube area) to enable flow to be restricted in case of flow instability. The liquid level for non-vacuum operations is maintained to the upper (top) tubesheet. This means the liquid level in the base of the distillation column must be higher, and the column must be elevated above the ground. For vacuum applications, the liquid level may be dropped to 0.3 – 0.6 times the tube length. Vapor – liquid mixture leaves the reboiler and separation takes place in the column.

The horizontal thermosiphon reboiler, as shown in Figure 23D, has a TEMA X, G, H, or E shell, single or two-tube passes, and boiling takes place on the shell side. Flow is restricted in the inlet line for stable operation and good control of the reboiler.

Forced Circulation Reboilers. These reboilers are used for heavy fouling, viscous, or solid-bearing liquids, or when the vaporization rate is low. The pump in the liquid feed line to the reboiler is used to circulate the fluid through the system. The boiling fluid is on the tube side in most cases, but may be on the shell side in special applications. The reboiler may be horizontal or vertical. Generally, very little boiling (< 1 %) takes place within the reboiler due to the high circulation rate.

The foregoing four major types of reboilers are compared in Table 3 for several important process conditions [20]. This table may be used for prescreening the type of reboiler before going through a detailed design.

2.2.2.3. Waste Heat Boilers

Waste heat boilers are used in recovering heat from the flue gas, or for cooling and controlling of chemical process gases by generating steam. This steam can be used for industrial processes, power generation, or space heating. A combination boiler that operates both by firing fuel and by removing heat from a gas stream is also referred to as a waste heat boiler.

Waste heat boilers may be categorized as firetube and watertube units. In a *firetube boiler,* the hot gas flows through the tubes, and a water – steam mixture flows outside the tubes. In a *watertube boiler*, the water – steam mixture flows through the tubes and the hot gas flows outside the tubes. Firetube boilers are designed with natural circulation, and watertube boilers with natural or forced circulation.

Firetube boilers are used to recover or remove heat from relatively high pressure, high temperature process gases. For example, in the steam – methane reforming process, the high pressure gas leaves the reformer at several hundred kPa and at 870 – 980 °C (1600 – 1800 °F). The boiler resembles a shell-and-tube type heat exchanger. Since high pressure steam is generated on the shell side, the shell and tube wall thickness should be chosen properly because both the shell and tube are pressurized.

The firetube boilers are generally limited to steam pressure of under 6.9 MPa (1000 psig). They are usually more economical than the watertube boilers if the flow area required is less than 0.4 m^2 (4 ft^2) since construction is relatively uncomplicated. The heat-exchanger effectiveness of firetube boilers usually ranges from 65 to 75 % [21].

Watertube boilers are used to recover heat from flue gases at near-atmospheric pressure. Nearly all watertube boilers have finned tubes; plain tubes are used for those watertube boilers having gases above 760 °C (1400 °F). The heat-exchanger effectiveness for watertube boilers with fins usually ranges from 90 to 95 %, and that for watertube boilers without fins from 65 to 75 % [21].

In natural circulation boilers, thermosiphon action or natural circulation results due to the density difference between the steam – water mixture in the steaming area and the water in the downcomer. In this case, watertubes are either vertical or inclined. When horizontal tubes are used in the boiler with vertical gas flow, forced circulation is mandatory since buoyant force is not sufficient to sustain natural circulation. Forced circulation is achieved with pumps.

Table 3. Reboiler selection guide [20]

Process conditions	Kettle or internal	Reboiler type		
		Horizontal shell-side thermosiphon	Vertical tube-side thermosiphon	Forced flow
Operating pressure				
Moderate	E	G	B	E
Near critical	B – E	R	Rd	E
Deep vacuum	B	R	Rd	E
Design ΔT				
Moderate	E	G	B	E
Large	B	R	G – Rd	E
Small (mixture)	F	F	Rd	P
Very small (pure component)	B	F	P	P
Fouling				
Clean	G	G	G	E
Moderate	Rd	G	B	E
Heavy	P	Rd	B	G
Very heavy	P	P	Rd	B
Mixture boiling range				
Pure component	G	G	G	E
Narrow	G	G	B	E
Wide	F	G	B	E
Very wide, with viscous liquid	F – P	G – Rd	P	B

Category abbreviations: B, Best; G, Good operation; F, Fair operation, but better choice is possible; Rd, Risky unless carefully designed, but could be best choice in some cases; R, Risky because of insufficient data; P, Poor operation; E, Operable but unnecessarily expensive.

Natural circulation boilers cost less, are easier to construct, and require minimum maintenance. The circulation ratio (water mass flow : steam mass flow) in natural circulation boilers varies from 15 : 1 to 25 : 1; the circulation ratio for forced convection boilers is restricted to 5 : 1 – 7 : 1 to minimize pump size and power consumption.

Firetube boilers have either horizontal tubes or vertical tubes, and most of them have natural circulation of the steam – water mixture. Usually they are heated by process gas. A variety of firetube boilers are available; further design details are presented in [22], [23].

Watertube boilers with vertical and inclined tube have natural circulation, and those with horizontal tubes have forced circulation; the latter are less reliable and more expensive. For boilers with natural circulation, either unfinned or finned ordinary tubes are used or bayonet unfinned tubes are used. Again, many types of watertube natural circulation boilers are available; further design details can be found in [22], [23].

3. Heat Exchanger Design Methodology

A methodology for designing a new heat exchanger is illustrated in Figure 24 [24]. Major design considerations include:

1) Process and design specifications
2) Thermal and hydraulic design
3) Mechanical design including operation and maintenance considerations
4) Manufacturing considerations and cost
5) Trade-off factors and system-based optimization

There could be strong interactions and feedback among the aforementioned considerations as indicated by the double-sided arrows in Figure 24. One example of these interactions is as follows.

Consider a shell-and-tube exchanger design with heavy fouling. In the *process specification* module, geometry and material are properly selected to minimize fouling and corrosion, and to facilitate cleaning. The heat exchanger can be positioned and oriented such that on-location cleaning or easy removal for external cleaning is possible. In thermal – hydraulic design,

Figure 24. Heat exchanger design methodology

the fouling resistance, and hence the amount of increased surface area required, should be properly taken into account depending upon the cleaning cycle schedule. For the mechanical design, proper material gages should be selected for the desired life of the exchanger from the fouling and corrosion point of view. Also, the cleaning and maintenance schedule should be decided. The tube gage could, in turn, affect both heat transfer and pressure drop. The material and gage selection as well as the cleaning cycle will impact the fixed and operating costs of the exchanger. Two aluminum heat exchangers may be less expensive than one titanium exchanger for the same total service time when using ocean water for cooling. This affects the geometry, thermal-hydraulic design, and mechanical design.

The overall design methodology is quite complex because many qualitative judgments in addition to quantitative calculations must be introduced. Further details on this methodology can be found in [24]. A number of these quantitative and qualitative design aspects are covered in this article.

4. Criteria for Heat Exchanger Selection

The four basic heat exchanger construction types are tubular, plate-type, extended surface, and regenerative as shown in Figure 1C. Selection of a particular exchanger for a specific service depends upon the evaluation of many and often conflicting process requirements. A list of some important design variables and general selection criteria are summarized below for design evaluation of one or more types of exchangers.

4.1. General Selection Criteria

4.1.1. Design Variables

The following factors can affect the selection of a heat exchanger:

1) Pressure: very high or very low pressures will eliminate some types, e.g., plates.
2) Temperature: if the temperature limits of the usual construction materials are exceeded, special and expensive alloys may be required.
3) Fluid Characteristics:
   a) Corrosive fluids and those requiring minimum contamination will require special construction materials.
   b) Very toxic fluids must be prevented from leaking into the other fluid or to the surroundings thus requiring special design.
   c) Flammable or those fluids having explosive tendencies must be kept in leakproof designs.
   d) The phase condition of the fluid, i.e., whether liquid, vapor, or a mixture of phases, will affect the suitability of certain types.
   e) Physical properties such as viscosity affect the heat transfer and pressure drop, and can therefore affect the exchanger selection.
   f) Fouling characteristics of the fluid will also affect the selection of exchanger.
4) The potential size of the exchanger can eliminate certain designs.
5) Temperature difference and/or temperature approach influence the selection of shell type, number of passes or exchangers in series, or even exchanger types such as compact designs.
6) Pressure drop: when pressure drop is a critical parameter, those types that can be accurately calculated are chosen.
7) Historical: often the exchanger type is based on prior plant experience with regard to performance and maintenance. Certain types or plant standards may then dictate standard sizes and types.

4.1.2. General Selection Guidelines

Shell-and-tube exchangers are very versatile. Any combination of gas, liquid, condensing or evaporating fluid, or two-phase fluid can be used on one or both sides of a shell-and-tube two-fluid exchanger. Operating pressures can vary from high vacuums to very high pressures ($>$ 14 MPa, i.e., 2000 psig). Operating temperatures can vary from cryogenics to ca. 1000 °C (1800 °F), a limit for most special metals. Heavy fouling, corrosive, or viscous fluids can be accommodated. The cost of the heat-transfer surface is relatively high for shell-and-tube exchangers.

Plate exchangers are used with liquids and condensing or evaporating fluids. Because of relatively high pressure drops associated with the corrugated plates, these exchangers are seldom used for gases. The operating pressure is limited to ca. 2.5 MPa (360 psig) but pressures below 1.0 MPa (150 psig) are more usual. Similarly, the operating temperature is limited, due to the gaskets, to ca. 260 °C (500 °F) but operation is usually < 150 °C (300 °F). Heavy fouling fluids can be accommodated. Generally, the plate exchangers are competitive in price to shell-and-tube exchangers when stainless steel and more exotic materials are used.

Plate – fin exchangers are used with gas, liquid, condensing or evaporating fluid, or two-phase fluids. The operating pressures are usually limited to 700 kPa (100 psig), although some exchangers with operating pressures of ca. 8 MPa (1200 psig) are commercially available. These exchangers are available with operating temperatures of up to 840 °C (1550 °F). Because of the small flow-passage size, heavy fouling fluids and corrosive fluids cannot be used for this type of exchanger. The cost of heat-transfer surface per unit area is, however, considerably lower compared to the shell-and-tube and plate exchangers.

Tube – fin exchangers are used with gas, liquid, condensing or evaporating fluid, or two-phase fluids. The operating pressures on the tube side can be very high, as with shell-and-tube exchangers. The highest operating temperature is limited by the type of bonding, the materials employed, and material thickness; usually it ranges from 100 – 500 °C (200 – 900 °F). Heavy fouling fluids can be accommodated on the tube side. The cost of heat-transfer surface per unit area is generally somewhat higher than that for the plate – fin exchangers because of the higher cost of tubing.

Regenerators are exclusively used for gases (including humid air); liquids cannot be used because of the fluid carryover and mixing. Operating pressures are limited to ca. 400 kPa (60 psig). Operating temperatures are limited to ca. 800 °C (1450 °F) for metal rotary regenerators, and up to 2000 °C (3600 °F) or higher for fixed matrix ceramic regenerators. Very low fouling fluids are used for compact rotary regenerators. Heavy fouling and corrosive exhaust gases can be used in fixed matrix regenerators. The cost of heat-transfer surface per unit area is the lowest for compact rotary regenerators.

The above criteria are not stringent, because more than one type of heat exchanger can be designed for a given application. The sale price of a heat exchanger depends on many factors other than engineering material, labor, and tooling equipment costs. A relatively noncompact tubular heat exchanger may weigh more and occupy more space than a compact plate – fin exchanger for specified performance and durability considerations. However, if the tubular exchanger costs less than the plate – fin exchanger, and cost is the most important criterion, the tubular exchanger will probably be selected for that application.

4.2. Shell-and-Tube Exchangers

The major components of a shell-and-tube exchanger are the tubes, baffles, shell, front-end head, rear-end head, and tubesheets. A large number of geometrical variables or types are associated with each component and these may affect selection.

4.2.1. Tubes

Shell-and-tube exchangers have either plain or finned tubes. The outside diameter (*OD*) of the TEMA [2] standard plain tubes ranges from 6.4 to 50.8 mm (1/4 – 2 in). The most common sizes are 15.9, 19.1, and 25.4 mm (5/8, 3/4, and 1 in) tube *OD*. From the heat transfer point of view, smaller diameter tubes yield higher heat-transfer coefficients and result in a more compact exchanger. They are also more economical than large diameter tubes. However, larger diameter tubes are easier to clean and are more rugged: the common sizes available represent a compromise. For mechanical cleaning, the smallest practical size is 19.1 mm (3/4 in). For chemical cleaning, smaller sizes can be used provided that the tubes never plug completely.

Finned tubes are either low in height (up to 1.6 mm or 1/16 in) or high in height (15.9 – 19.1 mm or 0.63 – 0.75 in) with the fin density ranging from 630 to 1575 fins/m (16 – 40 fins/in). The surface area of such a fin tube is ca. 2.5 – 7 times that of a bare tube.

The tube wall thickness is generally identified by the Birmingham Wire Gage (BWG) or Stubs Gage. The nominal tube gages range from 10 to 21 BWG (3.40 – 0.81 mm or 0.134 – 0.032 in) [2]. Steel tubes are usually several gages thicker than the nonferrous or alloy tubes. Two types of wall thickness are available: minimum wall and nominal wall. The "minimal wall" has at least the thickness specified by the gage at the thinnest point (zero under-tolerance) and an over-tolerance of 20 %. The "nominal wall" has the wall thickness within ± 10 % of the specified gage. For the same specified gage, the minimum wall is thicker and heavier than the nominal wall by about one gage. The selection of the tube thickness depends upon many factors, such as pressure, corrosion, cost, tube-to-tubesheet joining process, and pressure drop through the tubes.

Tube lengths range from 1.83 to 6.10 m (6 – 20 ft) or longer, in 0.61 m (2 ft) increments. The TEMA [2] standard lengths are 2.44, 3.66, and 4.88 m (8, 12, and 16 ft) although longer exchangers are made with tubes up to 12.2 – 24.4 m (40 – 80 ft).

The number of tubes depends on the fluid flow rates and the available pressure drop. The number of tubes is selected so that the tubeside velocity for water and similar liquids ranges from 0.9 to 2.4 m/s (3 – 8 ft/s) and the shellside velocity from 0.6 to 1.5 m/s (2 – 5 ft/s). The lower velocity limit is to avoid excessive fouling, and the upper velocity limit to minimize erosion. When sand and silt are present, the minimum velocity is kept high enough to prevent settling.

The number of tube passes depends on the available pressure drop. Higher velocities in the tube result in higher heat-transfer coefficients, at the expense of increased pressure drop compared to that for low velocity. Therefore, if the increased pressure drop is acceptable, it is desirable to have fewer but longer tubes (reduced flow area and increased flow length). Long tubes are accommodated in a short shell exchanger by multiple tube passes. The number of tube passes in a shell generally ranges from one to eight. The standard design has one, two, or four tube passes. In multipass designs, an even number of passes is generally used; odd number passes are uncommon, and may result in mechanical and thermal problems in fabrication and operation. The open lanes between passes should be designed so that the shell fluid flows perpendicular to them to eliminate fluid bypass. Care should be also exercised to drain and vent the tube side in a multitube pass unit.

Tubes are fastened to tubesheets by mechanical rolling, butt welding, edge welding, explosion welding, or hydraulic expansion [25]. If one of the fluids is highly corrosive, toxic, or hazardous, leakage of shell fluid to tube fluid or vice versa is not acceptable, in which case a double tubesheet design would be used [25].

4.2.2. Tube Pitch and Layout

The selection of tube pitch is a compromise between a close pitch for increased shellside heat transfer and surface compactness, and an open pitch for decreased shellside plugging and ease in shellside cleaning. In most shell-and-tube exchangers, the ratio of tube pitch to tube outside diameter varies from 1.25 to 2. The minimum value is restricted to 1.25 because the tubesheet ligament may become too weak for proper rolling of the tubes and may cause leaky joints. The recommended width of the ligaments depends on the tube diameter, thickness, and pitch; the values are provided by TEMA [2]. Typically, the minimum ligament width is 6.4 mm (1/4 in) when mechanical cleaning is required, and 3.2 mm (1/8 in) when no fouling is expected, although in the latter case also 6.4 mm ligament width is desired to maintain sufficient strength.

Standard tube layouts are shown in Figure 25. For identical tube pitch and flow rates, the tube layouts in decreasing order of shellside heat-transfer coefficient and pressure drop are 30°, 45°, 60°, and 90°. Thus the 90° layout will have the lowest heat-transfer coefficient and the lowest pressure drop.

The square pitch (45° or 90°) is used when jet or mechanical cleaning is necessary on the shell side; here, a minimum cleaning lane of 6.35 mm (1/4 in) is provided. The square pitch is generally not used in the fixed tubesheet design because no cleaning is needed. The triangular pitch provides a more compact arrangement, usually resulting in a smaller shell, and the strongest header sheet for a specified shellside flow area. Hence, it is preferred when the operating pressure difference between two fluids is large. If properly designed, it can be cleaned from six di-

	30° triangular staggered array	60° rotated triangular staggered array	90° square inline array	45° rotated square staggered array
Transverse tube pitch X_t	p_t	$\sqrt{3}\ p_t$	p_t	$\sqrt{2}\ p_t$
Longitudinal tube pitch X_l	$(\sqrt{3}/2)p_t$	$p_t/2$	p_t	$p_t/\sqrt{2}$
Ratio of minimum free flow area to frontal area, $A_0/A_{fr}=\sigma$	$(p_t-d_0)/p_t$	$(\sqrt{3}\ p_t-d_0)/\sqrt{3}\ p_t$ for $p_t/d_0 \geq 3.732$ $2(p_t-d_0)/\sqrt{3}\ p_t$ for $p_t/d_0 \leq 3.732$	$(p_t-d_0)/p_t$	$(\sqrt{2}\ p_t-d_0)/\sqrt{2}\ p_t$ for $p_t/d_0 \geq 1.707$ $2(p_t-d_0)/\sqrt{2}\ p_t$ for $p_t/d_0 \leq 1.707$

Figure 25. Nomenclature and geometric properties of tube banks common in shell-and-tube exchangers

rections instead of four, as in the square pitch arrangement. Where mechanical cleaning is required, the 45° layout is preferred for laminar or turbulent flow of a single-phase fluid, and for condensing fluid on the shell side. If the pressure drop is constrained on the shell side, the 90° layout is used for turbulent flow. Where boiling is necessary, the 90° layout, which provides vapor escape lanes, is preferred. However, if mechanical cleaning is not required, the 30° layout is preferred for single-phase laminar or turbulent flow and condensing involving a high ΔT range (a mixture of condensibles). The 60° layout is preferred for condensing involving a high ΔT range (generally pure vapor condensation) and for boiling applications. Horizontal tube bundles are used for shellside condensation or vaporization.

4.2.3. Baffles

Baffles may be classified into transverse and longitudinal types. The purpose of longitudinal baffles is to control the overall flow direction of the shell fluid. For example, F, G, and H shells have longitudinal baffles (see Fig. 4). The transverse baffles may be classified as plate baffles and rod (or strip) baffles. The plate baffles are used to support the tubes, to direct the fluid in the tube bundle at approximately 90° to the tubes, and to increase the turbulence of the shell fluid. Two types of plate baffles are shown in Figure 26, segmented and disk-and-doughnut. The rod baffles are used to support the tubes and to increase the turbulence of the shell fluid and are shown in Figure 27. The flow in a rod-baffled heat exchanger is parallel to the tubes, and the problem of flow-induced tube vibration is virtually eliminated by the baffle support of the tubes. The choice of baffle type, spacing, and cut are largely determined by flow rate, allowable pressure drop, tube support, and flow-induced vibration.

Plate Baffles. The two types of plate baffles are either segmental or disk-and-doughnut (Fig. 26). The single- and double-segmental baffles are most frequently used. The *single-segmental baffle* is generally simply referred to as a segmental baffle. The practical range of

Figure 26. Plate baffle types

Figure 27. Rod baffle supports

a) Skid bar; b) Tube; c) Rod; d) Rod or bar

single-segmental baffle spacing is one fifth to one shell diameter, though the optimum could be 40–50 % of the shell diameter. The minimum spacing is 50.8 mm (2 in) or one fifth of the shell diameter, whichever is larger. A spacing of 50.8 mm (2 in) is required for cleaning the bundle. Spacings closer than one fifth of the shell diameter provide added leakage (see Section 8.2.1) which nullifies the heat-transfer advantage of closer spacings. If the foregoing limits on the baffle spacing do not satisfy other design constraints such as $\Delta p_{\max}$ or tube vibration, no-tubes-in-window or pure crossflow design should be tried. The baffles are generally spaced between the nozzles, and do not cover the entire length of the tubes. The inlet and outlet baffle spacing is generally larger than the "central" baffle spacing due to the nozzle locations in the shell.

The segmental baffle is a circular disk (with baffle holes) with a segment removed. The baffle cuts, expressed as the percentage of the shell inside diameter, vary from 20 % to 49 %, the most common being 20 – 25 %. The baffle cut and spacing should be designed such that the flow velocity is approximately the same for the cross flow and window flow. At large baffle spacings, the percent cut may approach 45 – 49 % in order to avoid excessive pressure drop across the windows compared to the bundle. Large or small spacings coupled with large baffle cuts are undesirable because of the increased potential of fouling associated with stagnant flow areas. If fouling is of prime concern, the baffle cut should be kept < 25 % to maintain high velocity through the window zone. The direction of the baffle cut is selected as either horizontal (see Fig. 26) or vertical for a single-phase fluid (liquid or gas) on the shell side. For a very viscous liquid, the direction of the baffle cut should be horizontal for better mixing. The direction of the baffle cut is selected as vertical for the following shellside applications: condensation (for better drainage), evaporation/boiling (to promote more uniform flow), entrained solids in liquid (to provide the least interference for solids to fall out), and multishell pass exchangers (includes F shell).

Even though one of the major functions of the plate baffle is to include cross flow (flow normal to the tubes) for improved heat-transfer performance, this objective is only approximated. Various clearances are required for manufacturing. Fluid can leak through these clearance passages and reduce the heat-transfer effectiveness. Three clearances associated with a plate baffled shell-and-tube exchanger are tube-to-bundle hole clearance, baffle-to-shell clearance, and bundle-to-shell clearance.

The *tube-to-baffle hole* clearance should be kept at a minimum to reduce tube vibration and resultant damage as well as to minimize the A leakage stream (see Section 8.2.1). The clearance in terms of the difference between the baffle hole *ID* and tube *OD* is 0.40 mm (1/64 in) for unsupported tube length $L > 0.91$ m (36 in) or for the tube *OD* 31.8 mm (1.25 in) or smaller; this clearance is 0.80 m (1/32 in) for the unsupported tube length $L < 0.91$ mm (36 in) or for the tube $OD > 31.8$ mm (1.25 in). The *baffle-to-shell* clearance should be kept to a minimum to minimize the E leakage stream (see Section 8.2.1). The recommended maximum diametral clearance (shell *ID* minus baffle *OD*) varies from 2.5 mm (0.100 in) for 0.20 m (8 in) shell *ID* to 7.6 mm (0.300 in) for 1.52 m (60 in) shell *ID* [2]. From the strength and weldability viewpoints, the tube holes are kept some distance away from the edge of the tubesheet (shell *ID*) and hence from the baffle edge resulting in *bundle-to-shell* bypass stream C flowing around the edge (see Section 8.2.1). Sealing strips are used to block this space and force the bypass stream to flow through the tubes. The use of sealing strips is recommended every five to seven row of tubes in the bypass stream direction provided that the design is checked for flow-induced vibration of tubes near the sealing strips.

If the primary function of baffles is to support the tubes, they are referred to as "support plates". They may be thicker than the baffle, have less tube-to-baffle hole clearance, and provide greater stiffness to the bundle.

The *double-segmental baffle,* Figure 26, also referred to as a strip baffle, provides lower shellside pressure drop than that for the single-segmental baffle for the same unsupported tube span. Hence an exchanger with this type of baffle can handle larger fluid flows on the shell side. *Multi-segmental* baffles have a strong parallel flow component, provide a lower pressure drop, and permit closer tube support to prevent tube vibrations.

The lower pressure drop results in a large baffle spacing. Since the tubes in the window zone

are supported at a distance of two or more times the baffle spacing, they are most susceptible to vibration. To eliminate the susceptibility of tube vibrations and to reduce the shellside pressure drop, the tubes in the window zone are removed and support plates are used to reduce the unsupported span of the remaining tubes. The resultant design is referred to as the segmental baffle with no-tubes-in-window and support plates as shown in Figure 26. The low velocity regions in the baffle corners do not exist, resulting in good flow characteristics and less fouling. Thus the loss of heat-transfer surface in the window region is partially compensated for. However, the shell size must be increased to compensate for the loss in surface area in the window zone. If the shellside operating pressure is high, this no-tubes-in-window design is very expensive.

The *disk-and-doughnut baffle* is made up of alternate disk- and doughnut-shaped baffles as shown in Figure 26. Generally, the disk diameter is larger than the half shell diameter, and the diameter of the hole of the "doughnut" is smaller than the half shell diameter. This baffle design provides a lower pressure drop compared to a single-segmental baffle for the same unsupported tube span, and eliminates the tube bundle-to-shell bypass stream C. The disadvantages of this design are: (1) all tie rods to hold the baffles are within the tube bundle, and (2) the central tubes are supported by the disk baffles, which in turn are supported only by tubes in the overlap region of the larger diameter disk over the doughnut hole. This design is used in nuclear shell-and-tube exchangers.

Rod Baffles. A rod baffle is made up of parallel rods (a rod matrix) mounted on a baffle ring. The rod diameter is equal to the tube spacing (zero clearance), so that the baffle touches and constrains all tubes on four sides as shown in Figure 27. Thus, in a square layout, two vertical baffles constrain all tubes from two sides. The following two horizontal baffles constrain all tubes from the remaining two sides (90° to the first side). A set of four rod baffles (two vertical and two horizontal) is repeated in the exchanger. The rod baffle arrangements for both square and triangular tube layouts are shown in Figure 27. The baffle spacing is generally kept at 0.152 m (6 in) for single-phase applications and 0.305 m (12 in) for condensers and reboilers. Generally the tube diameters and tube pitches are selected so that the rod diameter is 4.8 mm (3/16 in) or 6.4 mm (1/4 in).

The rod baffle exchanger has several advantages over the plate-baffled exchanger, as follows: (1) It eliminates flow-induced tube vibrations since the tubes are rigidly supported at four successive points. (2) The pressure drop on the shell side is about one-half of that with a double-segmental baffle at the same flow rate and heat transfer rate. Alternatively, the rod baffle exchanger will result in a smaller unit for the same heat transfer and pressure drop. (3) There are no stagnant flow areas with the rod baffles, resulting in less fouling and corrosion, and improved heat transfer compared to that for a plate baffle exchanger. However, the rod baffle exchanger will require longer tubes of smaller diameter. If the tubeside fluid is controlling and has a pressure drop limitation, the rod baffle exchanger may not be applicable.

Figure 28. Impingement protection designs
A) Impingement plate; B) Impingement rods; C) Nozzle impingement baffle; D) Annular distributor [26]

Impingement Baffles. The most common cause of tube failure is the improper location and size of the impingement plate. Impingement baffles or plates are generally used in the shellside just below the inlet nozzle. They protect the tubes in the top row from erosion, cavitation, and vibration due to the impact of high velocity fluid jet from the nozzle to the tubes. One of the most common forms of this baffle is a solid circular plate located under the inlet nozzle just in front of the first tube row as shown in Figure 28A and C. The location of this baffle within the shell is critical in order to minimize

the associated pressure drop and high escape velocity. For this purpose, adequate areas should be provided both between the nozzle and plate and between the plate and tube bundle. This can be achieved by either omitting some tubes from the circular bundle as shown in Figure 28A or the nozzle contains an expanded section as shown in Figure 28C. Alternatively, impingement rods (Fig. 28B), dummy tubes, or thick-walled tubes are used. The annular distributor of Figure 28D is an excellent but expensive design. It permits higher velocities and any orientation of the nozzles.

4.2.4. Shells

Seven types of shells, as classified by the TEMA [2], are shown in Figure 4. The E shell is the most common as it is inexpensive and simple. In this shell, the shell fluid enters at one end of the shell and leaves at the other end, i.e., there is one pass on the shell side. The tubes may have single or multiple passes and are supported by transverse plate baffles. This shell is the most common for single-phase shell fluid applications. Multiple passes on the tube side and a single shell pass reduce the exchanger effectiveness or F factor over a single-pass arrangement. If it is too low, two E shells in series may be used to increase the mean temperature difference and the heat exchanger effectiveness ε.

The F shell has a longitudinal baffle, resulting in two shell passes and a pure counterflow arrangement. Although ideally this is a desirable flow arrangement, the F shell is rarely used in practice because there are many problems associated with the design. In particular, there will be heat transfer through the longitudinal baffle from the hot side to the cold side of the shell fluid; also if the longitudinal baffle is not continuously welded to the shell, or if seals are not provided between the longitudinal baffle and the shell, there will be leakage from the high pressure to the low pressure shell side. Both these factors will reduce the mean temperature difference and the exchanger effectiveness more than the gain by using the pure counterflow arrangement. It is also difficult to remove or replace the tube bundle. With the F shell, there are also additional problems of fabrication and maintenance. Hence, if one needs to increase the exchanger effectiveness, multiple shells in series are preferred over the F shell.

The G and H shells are related to the F shell, having variants of the longitudinal baffle. The double-split flow H shell is similar to the G shell, but with two inlet and two outlet nozzles (and two horizontal baffles) to accommodate high inlet velocities. The G and H shells are seldom used for shellside single-phase applications, since there is no advantage over E or X shells. They are used as horizontal thermosiphon reboilers, condensers, and other phase-change applications. The longitudinal baffle serves to prevent flashing out of the lighter components of the shell fluid, helps flushing out of noncondensables, provides increased mixing, and helps to distribute the flow. Generally, ΔT and Δp across the longitudinal baffles are small, and the heat transfer across the baffle and flow leakages from the sides have an insignificant influence on the performance. The H shell approaches the crossflow nozzle arrangement of the X shell, and it usually has low shellside Δp compared to that for the E, F, and G shells.

The divided flow J shell has two inlet and one outlet, or one inlet and two outlet nozzles. It has approximately one eighth the pressure drop of a comparable E shell, and is therefore used for low pressure drop applications such as a condenser in vacuum. For a condensing shell fluid, the J shell is used with two inlets for the gas phase and one central outlet for the condensates and leftover gases.

The K shell is used for partially vaporizing the shell fluid. It is used as a kettle reboiler in the process industry and as a flooded chiller in the refrigeration industry (see Section 2.2.2.2).

For a given flow rate and surface area, the crossflow X shell has the lowest shellside pressure drop compared to all other shell configurations except the K shell. Hence, it is used for gas heating and cooling with and without finned tubes and for vacuum condensation. It is also used when shell flows are large. No transverse baffles are used in the X shell; however, support plates are used to suppress the flow-induced vibrations. Flow distributions on the shell side can be a serious problem unless a proper provision has been made to feed the fluid uniformly at the inlet. This can be achieved by a single nozzle, multiple nozzles, or by keeping a clear lane

along the length of the shell near to the nozzle inlet as shown in Figure 29.

Figure 29. TEMA X shell with multiple nozzles with top tube rows omitted
a) Tube bundle; b) Tube support plates (baffles); c) Vapor distribution space; d) Perforated distributor plate

The type of shells described in Figure 4 has either one or two shell passes in one shell. The cost of the shell exceeds the cost of the tubes by far, hence a design should accommodate the required heat-transfer surface in one shell. Multipassing on the shell side with longitudinal baffles will reduce the flow area per pass compared to a single pass on the shell side in a single shell; this will result in higher shellside pressure drop. Hence instead, multiple shells in series are used for the following reasons: (1) For exchangers requiring high effectiveness, multipassing is the only alternative. (2) For part-load operations and where a spare bundle is essential, multiple shells (which may be of smaller size) will result in an economical operation. (3) Shipping and handling may dictate restrictions on the overall size or weight of the unit resulting in multiple shells for an application. In heat recovery trains and some other applications, up to six shells in series are commonly used. The limitation on the number of shells in such applications is the pressure drop limit on one of the streams.

4.2.5. Front-End Heads

The front-end head is stationary, while the rear-end head could be either stationary or floating depending upon the thermal stresses between the tubes and the shell. The major criteria for the selection of front-end and rear-end heads are the thermal stresses, operating pressures, cleanability, hazards, and cost.

The front-end heads are primarily of two types, the channels and the bonnet, as shown in Figure 4. The bonnet head B is cast in one piece and has either a side-entering or end-entering nozzle. Although the bonnet head is less expensive, the inspection and maintenance requires a breaking of the pipe joints and a removal of the bonnet. Hence, the bonnet head is generally used for clean tubeside fluids. The channel head can be removable as in the A head, or can be integral with the tubesheet as in C and N heads. There is a removable channel cover in these front-end heads to allow inspection and maintenance without disturbing the piping. The nozzles are side-entering in these types. The shell is welded onto the N head, but is flanged to the C head. In the N head, no joint exists between the channel and the tubesheet and between the tubesheet and the shell, thus eliminating any leakage between the shell and the tubes. The D head has a special high pressure closure and is used when pressures of 2100 kPa (300 psig) and higher are necessary.

4.2.6. Rear-End Heads

In a shell-and-tube exchanger, the shell is at a temperature different from the tubes because of the heat transfer between the shell and tube fluids. These would result in a differential thermal expansion and stresses in the shell, tubes, and the tubesheet. If proper provision is not made, buckling of the shell or tubes would result, or tubes would be pulled apart or out of the tubesheet. The provision for the differential thermal expansion is made in the rear-end heads. Basically, they may be categorized as fixed or floating rear-end heads depending on whether provisions are absent or present for differential thermal expansion, respectively.

A heat exchanger with fixed rear-end heads L, M, or N has a fixed tubesheet on that side. Hence, the overall design is rigid. The tube bundle-to-shell clearance is the smallest compared to other designs, thus minimizing the bundle-to-shell bypass stream C. Any number of tube passes can be employed. The major disadvantages of the fixed tubesheet exchanger are described as follows: since there is no relief of thermal stresses between the tubes and the shell, the fixed tubesheet exchangers are used where relatively low temperatures ($\leq 315\,^{\circ}$C or $600\,^{\circ}$F) coupled with low pressures (≤ 2100 kPa or 300 psig) are required, with the inlet temperature difference between the two fluids being $\lesssim 50$–$60\,^{\circ}$C ($100\,^{\circ}$F). With expansion bellows, the inlet temperature difference between two fluids can be increased to ca. 80–$90\,^{\circ}$C ($150\,^{\circ}$F). However, bellows are generally not available for all shell sizes and operating pressures. In fact, they are uneconomical for high pressures (> 4150 kPa or 600 psig). The fluid should be clean on the shell side or the shell side should be cleanable by the chemical cleaning methods. If it is essential to prevent possible leakage between the two fluid streams, double tubesheets are used. The fixed tubesheet exchanger is a low cost unit after the U-tube exchanger.

The differential thermal expansion can be accommodated by a floating rear-end head in which the tubes expand freely within the shell thus eliminating thermal stresses. The tube bundle can also be removed for cleaning the shell side. Basically, there are three types of floating rear-end heads: U-tube head, internal floating heads (pull-through or split ring heads), and outside packed floating heads.

In the *U-tube bundle,* the thermal stresses are almost eliminated due to free expansion of the U tubes, and the rear-end head has an integral cover which is low in cost compared to other rear-end heads. The exchanger construction is simple, having only one tubesheet and no expansion joints, and hence it is the lowest cost design. The tube bundle can be removed for shellside cleaning or replaced; however, it is difficult to remove a U-tube from the bundle except in the outer row, and it is also difficult to mechanically clean the tubeside bends. So a U-tube exchanger is used with clean fluids inside the tubes unless the tube side can be chemically cleaned. Flow-induced vibration can also be a problem for the tubes in the bend region in the outermost row because of a long unsupported span, particularly in large diameter bundles.

The next simplest floating head is the *pull-through head* T as shown in Figure 4 with its own bonnet head. The tube bundle can easily be removed from the shell by first removing the front-end head. Individual tubes or the tube bundle can also be replaced if required. Because of the floating head bonnet flange and bolt circle, many tubes are omitted from the tube bundle near the shell. This results in the largest bundle-to-shell clearance or a significant bundle-to-shell bypass stream C. In order not to reduce the exchanger performance, sealing strips (or dummy tubes or tie rods) in the bypass area are essential. However, localized high velocities near the sealing strips could cause flow-induced tube vibration; hence, proper care must be exercised for the design. Since this design has the least number of tubes in a bundle for a given shell diameter compared to other floating head designs, the shell diameter is somewhat larger to accommodate a required amount of surface area. One of the ideal applications of the T head design is in the kettle reboiler for which there is ample space on the shell side, and the flow bypass stream C is of no concern (see Fig. 3E, AKT).

The large bundle-to-shell clearance can be minimized by bolting the floating head bonnet to a split backing ring (flange) as shown in Figure 3A (AES). It is referred to as an S rear-end head. The shell cover over the tube floating head has a diameter larger than the shell. As a result, the bundle-to-shell clearances are reasonable and sealing strips are generally not required. However, both ends of the exchanger must be disassembled for cleaning and maintenance. In both S and T heads, the shell fluid is held tightly to prevent the leakage to the outside. However, internal leakage is possible due to the failure of an internal hidden gasket, and is not easily detectable. The T head has more positive gasketing between the two streams than the S head. Both S and T head configurations are used for the tubeside multipass exchangers; the single-pass construction is not feasible if the advantages of the positive sealing of S and T heads are to be retained. The cost of S and T head designs is relatively high compared to the U tube or fixed tubesheet units. The cost for S heads is higher than for T heads. The split backing ring

floating head is extensively used in the petroleum industry for moderate operating pressures and temperatures. For very high operating pressures and temperatures, the S head design has a special test ring [2].

In the *outside packed floating head P* design of Figures 3C (AEP) and 4, the stuffing box provides a seal against the skirt of the floating head and prevents shellside fluid leakage to the outside. This skirt (and the tube bundle) is free to move axially against the seal to account for thermal expansion. A split ring flange near the end of the skirt seals the back end of the chamber. Because of the specific design of this floating head, any leak (either from the shell side or the tube side) at the gaskets is to the outside. Hence, the P head is generally not used with very toxic fluids. In this design, the bundle-to-shell clearance is large (ca. 38 mm or 1.5 in); as a result, sealing strips are required. The P head exchanger is more expensive that the W head exchanger.

The *packed floating head with lantern ring* or W head is shown in Figures 3F (AJW) and 4. Here a lantern ring rests on the machine surface of the tubesheet and provides an effective seal between the shellside and tubeside flanges. Vents are usually provided in the lantern ring to help locate any leaks in the seals before the shellside and tubeside fluids are allowed to mix. Where severe fluctuations in the heat duty are expected, the W head is not used since the packing could be loosened. Although single-pass design on the tubeside is possible, generally an even number of tube passes are used. The W head exchanger is the least expensive design of all floating heads. Although its cost is higher than the U tube bundle, this is offset by the accessibility to the tube ends for cleaning and repair; consequently, this design is sometimes used in petrochemical and process industries.

A large number of combinations of the front-end and rear-end heads with different shell types of Figure 4 are possible depending upon the application and the manufacturer. Some common types of combinations are shown in Figure 3.

4.2.7. Nozzles

Nozzle sizes are related to the piping size, the exchanger shell design (Fig. 28), and the escape flow area into the tube bundle. This escape area should have $\varrho v^2 < 6000\,\mathrm{kg\ m^{-1}\,s^{-2}}$ ($4000\,\mathrm{lbm\ ft^{-1}\,s^{-2}}$). It is the total free area between a nozzle and the projected area on the tube bundle. Sometimes tubes may be removed to obtain sufficient area. This sizing can not be made until some mechanical drawings have been made. The location of the nozzle with respect to the shell flanges is determined by pressure vessel codes.

5. Basic Heat-Transfer and Pressure-Drop Analysis

5.1. Basic Equations and Definitions of Heat-Transfer Analysis

In order to determine heat transfer and inlet or outlet temperatures in a heat exchanger, the basic equations used are the energy (and mass) conservation and the rate equations, either in a differential or integrated form. Referring to Figure 30, the temperature drop $\mathrm{d}T_\mathrm{h}$ of the hot fluid and the temperature rise $\mathrm{d}T_\mathrm{c}$ of the cold fluid across a differential element $\mathrm{d}x$ for an exchanger having any arbitrary flow arrangement are given by

$$\mathrm{d}q = q''\,\mathrm{d}A = -C_\mathrm{h}\,\mathrm{d}T_\mathrm{h} = \pm C_\mathrm{c}\,\mathrm{d}T_\mathrm{c} \tag{1}$$

Figure 30. Nomenclature for heat exchanger variables

Here $\mathrm{d}q$ is the heat transfer from the hot fluid to the cold fluid across the surface area $\mathrm{d}A$; C_h and C_c are the heat capacity rates for the hot and cold fluids, and the $\pm$ sign depends upon whether $\mathrm{d}T_\mathrm{c}$ is increasing or decreasing with increasing $\mathrm{d}A$.

The overall rate equation in a differential form (on a local basis) is

$$\mathrm{d}q = q''\,\mathrm{d}A = U\,(T_\mathrm{h} - T_\mathrm{c})_\mathrm{local}\,\mathrm{d}A = U\,\Delta T\,\mathrm{d}A \tag{2}$$

Here U is the overall heat-transfer coefficient.

Equations (1) and (2) in an integrated form for a heat exchanger are

$$q = C_h\left(T_{h,i} - T_{h,o}\right) = C_c\left(T_{c,o} - T_{c,i}\right) \tag{3}$$

and

$$q = UA\Delta T_m = \frac{\Delta T_m}{\boldsymbol{R}_o} \tag{4}$$

The true temperature difference ΔT_m depends on the exchanger configuration (flow arrangement) and the degree of fluid mixing within each fluid stream. The reciprocal of the overall thermal conductance *UA* is referred to as the overall thermal resistance $\boldsymbol{R}_o$. The mean overall heattransfer coefficient is defined as

$$U_m = \frac{1}{A}\int_A U\,dA \tag{5}$$

Unless explicitly mentioned, U_m is used throughout this article simply as U. This is because a constant and uniform U is idealized in the simplified theory as well as experimentally obtained. Note that the integration of Equation (2) with the definition of U_m from Equation (5) will yield Equation (4) with the following correct definition of ΔT_m

$$\frac{1}{\Delta T_m} = \frac{1}{q}\int_q \frac{dq}{dT} \tag{6}$$

The overall thermal resistance $\boldsymbol{R}_o$ consists of component resistances in series as shown in Figure 31.

$$\begin{aligned}\frac{1}{UA} &= \boldsymbol{R}_o = \boldsymbol{R}_h + \boldsymbol{R}_{s,h} + \boldsymbol{R}_w + \boldsymbol{R}_{s,c} + \boldsymbol{R}_c \\ &= \frac{1}{(\eta_0 hA)_h} + \frac{1}{(\eta_0 h_s A)_h} + \boldsymbol{R}_w + \frac{1}{(\eta_0 h_s A)_c} + \\ &\quad \frac{1}{(\eta_0 hA)_c}\end{aligned} \tag{7}$$

where $\boldsymbol{R}_h$ = hot-side film convective resistance, $\boldsymbol{R}_{s,h}$ = hot-side scale (fouling) resistance, $\boldsymbol{R}_w$ = wall thermal resistance, $\boldsymbol{R}_{s,c}$ = cold-side scale (fouling) resistance, $\boldsymbol{R}_c$ = cold-side film convective resistance, η_o = the extended surface efficiency, and h_s = fouling coefficient (inverse of a fouling factor).

The wall thermal resistance $\boldsymbol{R}_w$ is

$$\boldsymbol{R}_w = \begin{cases} \dfrac{\delta}{A_w k_w} & \text{for a flat wall} \\[2ex] \dfrac{\ln(d_o/d_i)}{2\pi k_w L N_t} & \text{for a circular tube with a single-layer wall} \\[2ex] \dfrac{1}{2\pi L N_t}\left[\displaystyle\sum_j \frac{\ln(d_{j+1}/d_j)}{k_{wj}}\right] & \text{for a circular tube with a multiple-layer wall} \end{cases}$$

where δ is the plate thickness, A_w is the total wall area for heat conduction, k_w is the thermal conductivity of the wall material, d_o and d_i are tube outside and inside diameters respectively, L is the tube length, and N_t is the number of tubes.

For a flat (or plain) wall associated with a plate – fin or an all prime surface exchanger,

$$A_w = L_1 L_2 N_p \tag{9}$$

where L_1, L_2, and N_p are the length, width, and total number of separating plates.

The extended surface efficiency η_o is

$$\eta_0 = 1 - \frac{A_f}{A}\left(1 - \eta_f\right) \tag{10}$$

where A_f = fin surface area, A = total (fin + primary) surface area on one side of the exchanger, and η_f = fin efficiency.

The expressions for η_f are provided in Table 4 for some common types of fins. The fin efficiency for continuous flat fins on an array of circular tube is obtained by a sector method [27]. In this method, the rectangular or hexagonal fin (see Fig. 32A or B) is divided into N sectors. Each sector i is considered as a circular fin (see Table 4) with the radius $r_{e,i}$ equal to the length of the centerline of the sector i. The fin efficiency η_f of the whole fin is then given by

$$\eta_f = \frac{\sum_{i=1}^{N} \eta_{f,i} A_{f,i}}{\sum_{i=1}^{N} A_{f,i}} \tag{11}$$

Only a few segments N (e.g., 8 – 10) will suffice to provide η_f accurately.

UA in Equation (7) is defined as

$$UA = U_h A_h = U_c A_c = U_w A_w \tag{12}$$

Thus U is defined optionally in terms of the hot fluid surface area A_h, the cold fluid surface area A_c, or the wall conduction area A_w. For a plain

Figure 31. Thermal circuit for a heat exchanger section

Figure 32. Flat fin over (A) an inline and (B) a staggered tube arrangement; the smallest representative segment of the fin for (C) an inline and (D) a staggered tube arrangement

tubular exchanger, U_o based on the tube outside surface area, from Equation (7), is given by

$$\frac{1}{U_o}=\frac{1}{h_0}+\frac{1}{h_{o,s}}+\frac{d_o \ln(d_o/d_i)}{2k_w}+\frac{d_o}{h_{i,s}d_i}+\frac{d_o}{h_i d_i} \quad (13)$$

Integration of Equations (1) and (2) for a heat exchanger configuration, when presented in a nondimensional form can be presented in four alternative methods referred to as ε – NTU, P – NTU, MTD, and ψ – P methods, see Section 5.2. The following idealizations are built into the results presented in Table 7.

1) The heat exchanger operates under steady-state conditions (i.e., constant flow rate, and thermal history of fluid particles independent of time).
2) Heat losses to the surroundings are negligible.
3) There are no thermal energy sources in the exchanger.
4) In counterflow and parallel-flow exchangers, the temperature of each fluid is uniform over every flow cross section. From the temperature distribution point of view, in crossflow exchangers, each fluid is considered mixed or unmixed at every cross section depending upon the specifications. For a multipass exchanger, the foregoing statements apply to each pass depending upon the basic flow arrangement of the passes; the fluid is considered mixed or unmixed between passes.
5) Either there are no phase changes (condensation or boiling) in the fluid streams flowing through the exchanger or the phase changes occur under one of the following conditions: (a) Phase change occurs at a constant temperature as for a single component fluid at constant pressure; the effective specific heat for the phase-changing fluid is infinity in this case, and hence $C_{\max} \to \infty$. (b) The temperature of the phase-changing fluid varies lin-

Table 4. Fin efficiency for plate – fin and tube – fin geometries of uniform fin thickness

Geometry	Fin efficiency formula $m_i = \left[\frac{2h}{k_f \delta_i}\left(1 + \frac{\delta_i}{l_{ef}}\right)\right]^{1/2}$ $E_i = \frac{\tanh(m_i l_i)}{m_i l_i}$ $i = 1, 2, 3, 4$
 Plain, wavy, or offset strip fin of rectangular cross section	$\eta_f = E_1$ $l_1 = \frac{b}{2} - \delta_1 \quad \delta_1 = \delta$
Triangular fin heated from one side	$\eta_f = \frac{h A_1 (T_0 - T_a) \frac{\sinh(m_1 l_1)}{m_1 l_1} + q_e}{\cosh(m_1 l_1)\left[h A_1 (T_0 - T_a) + q_e \frac{T_0 - T_a}{T_1 - T_a}\right]}$
 Plain, wavy, or louver fin of triangular cross section	$\eta = E_1$ $l_1 = \frac{l}{2}, \ \delta_1 = \delta$
 Circular fin	$\eta_f = \begin{cases} a(m l_e)^{-b} & \text{for } \Phi > 0.6 + 2.257(r^*)^{-0.445} \\ \frac{\tanh \Phi}{\Phi} & \text{for } \Phi \le 0.6 + 2.257(r^*)^{-0.445} \end{cases}$ $a = (r^*)^{-0.246} \quad \Phi = m l_e (r^*)^{\exp(0.13 m l_e - 1.3863)}$ $b = \begin{cases} 0.9107 + 0.0893 r^* & \text{for } r^* \le 2 \\ 0.9706 + 0.17125 \ln r^* & \text{for } r^* > 2 \end{cases}$ $m = \left(\frac{2h}{k_f \delta}\right)^{1/2} \quad l_e = l_f + \frac{\delta}{2} \quad r^* = \frac{r_e}{r_o}$
 Studded fin	$\eta_f = \frac{\tanh(m l_e)}{m l_e}$ $m = \left[\frac{2h}{k_f \delta}\left(1 + \frac{\delta}{w}\right)\right]^{1/2} \quad l_e = l_f + \frac{\delta}{2} \quad l_f = \frac{(d_e - d_o)}{2}$
Rectangular fin over circular tubes	See the text.

early with heat transfer during the condensation or boiling. In this case, the effective specific heat is constant and finite for the phase-changing fluid.

6) The specific heat of each fluid is constant throughout the exchanger so that the heat capacity on each side is treated as constant.
7) The velocity and temperature at the entrance of the heat exchanger on each fluid side are uniform.
8) For an extended-surface exchanger, the overall extended-surface temperature effectiveness η_o is considered uniform and constant.
9) The overall heat-transfer coefficient between the fluids is constant throughout the exchanger, including the case of phase-changing fluid in idealization 5.
10) The heat-transfer area is distributed uniformly on each fluid side. In a multipass unit, heat-transfer surface area is equal in each pass.

11) For a plate-baffled shell-and-tube exchanger, the temperature rise per baffle pass is small compared to the overall temperature rise along the exchanger, i.e., the number of baffles is large.
12) The fluid flow rate is uniformly distributed through the exchanger on each fluid side in each pass. No stratification, flow bypassing, or flow leakages occur in any stream. The flow condition is characterized by the bulk (or mean) velocity at any cross section.
13) Longitudinal heat conduction in the fluid and in the wall is negligible.

Idealizations 1 to 4 are necessary in a theoretical analysis of steady-state heat exchangers. Idealization 5 essentially restricts the analysis to single-phase flow on both sides or on one side with a dominating thermal resistance. For two-phase flow on both sides, many of the foregoing idealizations are not valid, since mass transfer in phase change results in variable properties and variable flow rates of each phase, and the heat-transfer coefficients vary significantly. As a result, the two-phase heat exchanger cannot be analyzed using the theory presented in this section. The design theory of two-phase exchangers is presented in Section 9.

If idealization 6 is not valid, the exchanger is divided into small segments until the specific heats can be treated as constant. Violation of idealization 7 is treated in Section 11. Idealization 8 is essential since no information is available on local variations of the heat-transfer coefficient h. The influences of idealizations 9 and 13 are discussed in Section 5.3; the influences of idealizations 10 – 12 are covered in [28].

If any of these idealizations are not valid for a particular exchanger application, the best solution is to work directly with either Equation (1) and (2) or their modified form by including a particular effect, and to integrate them over a small exchanger segment in which all of the idealizations are valid.

5.2. Dimensionless Methods for Exchanger Heat-Transfer Analysis

The results of integration of Equations (1) and (2) for exchanger configurations under the idealizations made just above can be presented in terms of three dimensionless groups. Based on the choice of the dimensionless groups, four methods have been evolved: ε – NTU, P – NTU, MTD, and $\psi - P$. The dimensionless groups for each method, their functional relationship, and how to compute q are summarized in Table 5 [28]. The relationships among the dimensionless groups are summarized in Table 6 [28]. A brief description of the dimensionless groups follows.

Table 6. Relationships between dimensionless groups of the P-NTU$_1$, MTD, and ψ-P methods and those of the ε-NTU method

$$P_1 = \frac{C_{\min}}{C_1}\varepsilon = \begin{cases} \varepsilon & \text{for} \quad C_1 = C_{\min} \\ \varepsilon C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$R_1 = \frac{C_1}{C_2} = \begin{cases} C^* & \text{for} \quad C_1 = C_{\min} \\ 1/C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$\mathrm{NTU}_1 = \mathrm{NTU}\frac{C_{\min}}{C_1} = \begin{cases} \mathrm{NTU} & \text{for} \quad C_1 = C_{\min} \\ \mathrm{NTU}\, C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$F = \frac{\mathrm{NTU}_{\mathrm{ef}}}{\mathrm{NTU}} = \frac{1}{\mathrm{NTU}(1 - C^*)} \ln \frac{1 - C^*\varepsilon}{1 - \varepsilon} \xrightarrow[C^* = 1]{} \frac{\varepsilon}{\mathrm{NTU}(1 - \varepsilon)}$$

$$F = \frac{1}{\mathrm{NTU}_1(1 - R_1)} \ln\left[\frac{1 - RP_1}{1 - P_1}\right] \xrightarrow[R_1 = 1]{} \frac{P_1}{\mathrm{NTU}_1(1 - P_1)}$$

$$\psi = \frac{\varepsilon}{\mathrm{NTU}} = \frac{P_1}{\mathrm{NTU}_1} = \frac{FP_1(1 - R_1)}{\ln[(1 - R_1 P_1)/(1 - P_1)]} \xrightarrow[R_1 = 1]{} F(1 - P_1)$$

The *heat-exchanger effectiveness* ε is an efficiency factor and has a thermodynamic significance. It is the ratio of actual heat transfer from the hot to the cold fluid in any exchanger configuration to the thermodynamically limited maximum possible heat transfer [19]. It is also the temperature effectiveness of the $C_{\min}$ fluid. Its value ranges from 0 to 1.

The *number of transfer units* NTU is a ratio of the overall conductance UA to the smaller heat capacity rate $C_{\min}$ (minimum of C_{h} and C_{c}). It designates the dimensionless "thermal size" of the exchanger. It may be interpreted as the $C_{\min}$ fluid dimensionless residence time, a temperature ratio, or a modified Stanton number [29]. Its value can range from 0 to ∞. For most process exchangers, its value ranges from ca. 0.5 to 2.

The *heat capacity rate ratio* C^* is simply a ratio of the smaller to larger heat capacity rates of the two fluids such that $C^* \leq 1$.

The *temperature effectiveness* or *thermal effectiveness* P of a fluid in an exchanger is the

Table 5. General functional relationships and dimensionless groups for ε-NTU, P-NTU, MTD, and ψ-P methods [28]

ε-NTU method	P-NTU method

$\varepsilon = \varphi(\text{NTU}, C^*, \text{flow arrangement})$	$P_1 = \varphi(\text{NTU}_1, R_1, \text{flow arrangement})$
$\varepsilon = \dfrac{C_h(T_{h,i} - T_{h,o})}{C_{\min}(T_{h,i} - T_{c,i})} = \dfrac{C_c(T_{c,o} - T_{c,i})}{C_{\min}(T_{h,i} - T_{c,i})}$	$P_1 = \dfrac{T_{1,o} - T_{1,i}}{T_{2,i} - T_{1,i}}$
$\text{NTU} = \dfrac{UA}{C_{\min}} = \dfrac{1}{C_{\min}} \int_A U\,dA$	$\text{NTU}_1 = \dfrac{UA}{C_1} = \dfrac{[T_{1,o} - T_{1,i}]}{\Delta T_m}$
$C^* = \dfrac{C_{\min}}{C_{\max}} = \dfrac{(Wc_p)_{\min}}{(Wc_p)_{\max}}$	$R_1 = \dfrac{C_1}{C_2} = \dfrac{T_{2,i} - T_{2,o}}{T_{1,o} - T_{1,i}}$
MTD method	**ψ-P method**
$q = UAF\Delta T_{lm}$	$q = UA\psi(T_{h,i} - T_{c,i})$
$\text{LMTD} = \Delta T_{lm} = \dfrac{\Delta T_1 - \Delta T_2}{\ln(\Delta T_1/\Delta T_2)}$	$\psi = \varphi(P_1, R_1, \text{flow arrangement})$
$\Delta T_1 = T_{h,i} - T_{c,o} \quad \Delta T_2 = T_{h,o} - T_{c,i}$	$\psi = \dfrac{\Delta T_m}{T_{h,i} - T_{c,i}}$
$F = \Phi(P_1, R_1, \text{flow arrangement}) \quad F = \dfrac{\Delta T_m}{\Delta T_{lm}}$	P_1 and R_1 are defined in the P-NTU method
P_1 and R_1 are defined in the P-NTU method	

ratio of the temperature rise (or drop) of that fluid stream to the inlet temperature difference of two fluid streams $P = \varepsilon$ for the $C_{\min}$ fluid, and $P = \varepsilon C^*$ for the $C_{\max}$ fluid. Thus $P \leq \varepsilon$ depending on the value of P for the $C_{\min}$ or $C_{\max}$ side.

The heat capacity rate ratio of the two fluid streams is designated as $R : R_1 = C_1/C_2$; $R_2 = C_2/C_1$; and R can range from 0 to ∞.

The *log-mean temperature difference correction factor* F, also referred to as the *exchanger configuration factor,* is a ratio of the true (actual) mean temperature difference in an exchanger to the log-mean temperature difference (LMTD). The LMTD is defined in Table 5 for all exchanger configurations except for a single-pass parallel flow exchanger for which $\Delta T_1 = T_{h,i} - T_{c,i}$ and $\Delta T_2 = T_{h,o} - T_{c,o}$. It must be emphasized that F does not represent the effectiveness or efficiency of an exchanger, i.e., $F = 1$ does not mean that the exchanger is 100 % efficient. It represents a degree of departure in the true mean temperature difference for a given exchanger from the counterflow log-mean temperature difference. The value of F ranges from 0 to 1; its value is maintained approximately at ≥ 0.8 in a good design.

The ψ factor is the ratio of the true mean temperature difference in an exchanger to the inlet fluid temperature difference. Its value ranges from 0 to 1.

The results for a variety of configurations for the $\varepsilon-$NTU, $P-$NTU, MTD, or $\psi-P$methods are available in the literature. The results for process industry configurations are provided in Table 7 for the $P-$NTU method. Similar results for the $\varepsilon-$NTU or $\psi-P$ methods are available in [28] and for the MTD and $\psi-P$ methods in [30].

In Table 7, those configurations that are stream symmetric are clearly indicated. For a stream symmetric configuration, reversing the flow direction of one or both fluid streams or interchanging the fluid streams (i.e., switching fluid 1 to the fluid 2 side and fluid 2 to fluid 1 side) will not change the expression for P_1. For example, $1-2$ shell-and-tube exchangers with shell fluid mixed (TEMA E shell) have stream symmetry. Hence, fluid 1 can flow either in the tubes or on the shellside; its temperature effectiveness P_1 is given by Equation (3.1) in Table 7. This is not true, for example, for the divided flow $1-2$ exchanger with the shell fluid mixed (TEMA G shell). Here fluid 1 must be the shellside fluid,

and P_1, NTU_1, and R_1 refer to the shellside fluid. For the tube fluid, P_2, NTU_2 and R_2 should then be computed from

$$P_2 = P_1 R_1, R_2 = 1/R_1, \mathrm{NTU}_2 = \mathrm{NTU}_1 R_1 \tag{14}$$

The relationship between the F factor, P_1, R_1, and NTU_1 is presented in Table 6 which is valid for all single-pass and multipass exchangers. However, when the exchangers are arranged in series, the F factors of individual exchangers are related to the overall F factor for all exchangers combined, as shown in Equation (4.2.4) of Table 7.

For a plate exchanger, when the number of thermal plates N is greater than ca. 40, its effectiveness approaches that of a plate exchanger with an infinite number of thermal plates [31]. Since most plate exchangers have the number of thermal plates $N > 40$, the asymptotic temperature effectiveness of single-pass and multipass exchangers are available [32].

5.3. Extensions of the Basic Heat-Transfer Theory

A number of idealizations mentioned in Section 5.1 have been relaxed and theoretical results are obtained which represent extensions to the basic theory. Two such results are summarized next. The influence of unequal pass areas, shellside baffle passes, and shell fluid bypassing is covered in [28].

5.3.1. Longitudinal Wall Heat Conduction

Longitudinal wall heat conduction in the opposite direction to fluid flow reduces the mean temperature difference in the exchanger and the exchanger effectiveness. This effect is primarily important for exchangers having a steep temperature gradient ($\Delta T/L$) in the flow direction, i.e., exchangers having high effectiveness ($> 75\,\%$) per pass and a short flow length L for the pass. The influence of longitudinal conduction is reported in the heat exchanger literature in terms of the $\varepsilon-\mathrm{NTU}$ method for single-pass counterflow and single-pass crossflow exchangers with both fluids unmixed. For the single-pass counterflow exchanger, the exchanger effectiveness, including the effect of longitudinal conduction, for $C^* = 1$ and $0.1 \le \eta_o hA \le 10$ is [33]:

$$1-\varepsilon = \frac{1}{1 + \mathrm{NTU}\,\frac{1+\lambda[\lambda\mathrm{NTU}/(1+\lambda\mathrm{NTU})]^{1/2}}{1+\lambda\mathrm{NTU}}} \tag{15}$$

where $\lambda = k_w A_k / L\, C_{\min}$ and A_k is the total wall cross-sectional area for longitudinal conduction.

The exchanger ineffectiveness $(1-\varepsilon)$ of Equation (15) is shown in [28], [29]. For $0.8 \le C^* \le 1$, the following correlation for ε is obtained [33]:

$$1-\varepsilon = \frac{1-C^*}{\Psi \exp(r_1) - C^*} \tag{16}$$

where

$$r_1 = \frac{(1-C^*)\,\mathrm{NTU}}{1+\lambda\mathrm{NTU}C^*} \tag{17}$$

$$\Psi = \frac{1+\gamma\Psi^*}{1-\gamma\Psi^*}; \Psi^* = \left(\frac{\alpha}{1+\alpha}\right)^{1/2} \frac{1+\gamma}{1/\alpha - \gamma - \gamma^2} \tag{18}$$

$$\gamma = \left(\frac{1-C^*}{1+C^*}\right)\left(\frac{1}{1+\alpha}\right); \alpha = \lambda\mathrm{NTU}C^* \tag{19}$$

Although Equation (16) is derived for $(\eta_o hA)^* = 1$, if $0.5 \le (\eta_o hA)^* \le 2$, the error introduced in the ineffectiveness $(1-\varepsilon)$ is within 0.8 % and 4.7 % for $C^* = 0.95$ and 0.8, respectively.

The effectiveness of a single-pass crossflow exchanger with both fluids unmixed, including the effect of longitudinal heat conduction, has been determined by Chiou [34]; the results are also available in [28].

For a multipass exchanger, the effect of longitudinal heat conduction is included in determining individual pass effectivenesses, as already mentioned. The individual pass effectivenesses are in turn are used to compute the effectiveness of a multipass exchanger.

5.3.2. Variable Overall Heat-Transfer Coefficients

The theory and results of Section 5.2 are valid for constant and uniform overall heat-transfer coefficient U. In fact, individual heat-transfer coefficients (on which U depends) could be strongly dependent on the flow Reynolds number, heat-transfer surface geometries, fluid physical properties, and operating temperatures and pressures. Particularly for viscous liquids and boiling or

* Table condensed from R. K. Shah and A. Pignotti: *Basic Thermal Design of Heat Exchangers*, National Science Foundation Report, Int-8601771, 1988.

In this table, all variables, except P_1, R_1, NTU_1, and F, are local or dummy variables not necessarily related to similar ones defined in the list of symbols given at the beginning of this article.

condensing fluids, h and U may vary strongly in the exchanger. The influence of some specific variations in U are now summarized.

For a single-pass counterflow exchanger, if U varies linearly with a temperature of either fluid or if it varies linearly with local T_x, the mean overall heat-transfer coefficient U_m is [35]:

$$\frac{q}{A}=U_m \Delta T_{lm}=\frac{U_2 \Delta T_1 - U_1 \Delta T_2}{\ln\left[(U_2 \Delta T_1)/(U_1 \Delta T_2)\right]} \tag{20}$$

where U_1 and U_2 are the values on the ends of the exchanger having temperature differences of ΔT_1 and ΔT_2.
U_m in Equation (20) is a good approximation for very viscous liquids and partial condensation.

If U varies linearly with the surface area A, integration of Equation (5) will yield

$$U_m=(U_1+U_2)/2 \tag{21}$$

If $1/U$ varies linearly with T_x, U_m is given by [7]:

$$\frac{1}{U_m}=\frac{1}{U_1}\frac{\Delta T_{lm}-\Delta T_2}{\Delta T_1-\Delta T_2}+\frac{1}{U_2}\frac{\Delta T_1-\Delta T_{lm}}{\Delta T_1-\Delta T_2} \tag{22}$$

If U_1 and U_2 do not vary significantly, Equation (21) is a good approximation. However, if they do vary considerably for condensers, Equation (22) is recommended. If a question arises as to which of the three Equations (20), (21), or (22) should be used, the exchanger should be divided into a number of sections, and for each section U should be treated as either a constant or an arithmetic mean.

For a single-pass crossflow exchanger, SIEDER and TATE [36] proposed to modify Equation (20) by the F factor when U varies linearly with T_c, T_h, or T_x:

$$q=U_m A F \Delta T_{lm} \tag{23}$$

where U_m is given by Equation (20). This equation provides the results within about 10 % accuracy in the practical ranges of F [37]. ROETZEL [38] has provided specific results and correlations for several cases of variable coefficients.

For multipass shell-and-tube exchangers with variable U, GARDNER and TABOREK [37] recommend the use of Equation (23) with appropriate values of F for the specific exchanger. Some specific results for the 1 – 2 exchanger with shell fluid mixed (TEMA E) are presented graphically in [28] in terms of $\psi - P$ charts.

5.4. Exchanger Pressure-Drop Analysis

Usually a fan, blower, or pump is used to promote fluid flow through individual sides of a heat exchanger. The required fluid pumping power is important for gases and viscous liquids. The fluid pumping power $\tilde{P}$ is approximately related to the core pressure drop in the exchanger [27]:

$$\tilde{P}=\frac{W\Delta p}{p}\approx\begin{cases}\dfrac{1}{2g_c}\dfrac{\mu}{\varrho^2}\dfrac{4L}{D_h}\dfrac{W^2}{D_h A_o} f\,Re & \text{for laminar flow} \quad (24a)\\[2ex] \dfrac{0.046}{2g_c}\dfrac{\mu^{0.2}}{\varrho^2}\dfrac{4L}{D_h}\dfrac{W^{2.8}}{A_o^{1.8}D_h^{0.2}} & \text{for turbulent flow} \quad (24b)\end{cases}$$

It is clear from Equations (24 a) and (24 b) that the fluid pumping power is strongly dependent upon the fluid density (particularly for low density fluids) in laminar and turbulent flows, and upon the viscosity in laminar flow. In addition, the pressure drop itself can be an important consideration when blowers and pumps are used for the fluid flow since they are head-limited. Also for condensing or evaporating fluids, the pressure drop affects the saturation temperature which in turn affects the heat-transfer rate. Hence, determination of the pressure drop in the exchanger is important.

The pressure drop associated with a heat exchanger consists of core (matrix or a portion with active heat-transfer surface) pressure drop and the pressure drop associated with the fluid distribution devices such as inlet and outlet manifolds, headers, tanks, nozzles, ducting, etc.

The core pressure drop is determined separately on each fluid side. It consists of one or more of the following components depending on the exchanger construction: (1) frictional losses associated with fluid flow over the heat-transfer surface (this usually consists of skin friction plus form drag), (2) momentum effect (pressure drop or rise due to the fluid density changes in the core), (3) pressure drop associated with sudden contraction and expansion at the core inlet and outlet, and (4) gravity effect due to the change in elevation between the inlet and outlet of the exchanger. The gravity effect is generally negligible for gases. For vertical liquid flows through

the exchanger, the pressure drop or rise ("static head") due to the elevation change is given by

$$\Delta p = \pm \frac{\varrho_m g L}{g_c} \tag{25}$$

where the "+" sign denotes vertical upflow (i.e., pressure drop), the "−" sign denotes vertical downflow (i.e., pressure rise), g is the gravitational acceleration, and L is the exchanger length.

The first three components of the core pressure drop are now discussed for several major exchangers. The pressure drop on the shellside of a shell-and-tube exchanger is presented in Section 8.2.1.

5.4.1. Plate – Fin Exchangers

For the plate-fin exchanger, all three components are considered in the core pressure drop evaluation [39]:

$$\frac{\Delta p}{p_1} = \frac{G^2}{2 g_c} \frac{1}{p_1 \varrho_1} \Bigg[\underbrace{(1 - \sigma^2 + K_e)}_{\text{entrance effect}} + \underbrace{f \frac{L}{r_h} \varrho_i \left(\frac{1}{\varrho}\right)_m}_{\text{core friction}} + \underbrace{2\left(\frac{\varrho_i}{\varrho_o} - 1\right)}_{\text{flow acceleration}} - \underbrace{(1 - \sigma^2 - K_e) \frac{\varrho_i}{\varrho_o}}_{\text{exit effect}} \Bigg] \tag{26}$$

where f is the Fanning friction factor (see Table 8), K_c and K_e are flow contraction (entrance) and expansion (exit) loss coefficients [39], G is fluid mass velocity (W/A_o), and σ is a ratio of minimum free flow area to frontal area.

K_c and K_e for four different entrance flow passage geometries are presented in [27], [39]. The entrance and exit losses are important at low values of σ and L (short cores), high values of Re, and for gases; they are negligible for liquids. The values of K_c and K_e presented in [27], [39] apply to long tubes for which flow is fully developed at the exit. For partially developed flows, K_c is lower and K_e is higher than that for fully developed flows. For interrupted surfaces, flow is never fully developed. For highly interrupted fin geometries, the entrance and exit losses are generally small compared to the core pressure drop, and the flow is well mixed; hence, K_c and K_e for $Re \to \infty$ should represent a good approximation.

The mean specific volume V_m or $(1/\varrho)_m$ in Equation (26) is given as follows: For liquids with any flow arrangement, or for a perfect gas with $C^* = 1$ and any flow arrangement (except for parallel flow),

$$\left(\frac{1}{\varrho}\right)_m = V_m = \frac{V_i + V_o}{2} = \frac{1}{2}\left(\frac{1}{\varrho_i} + \frac{1}{\varrho_o}\right) \tag{27}$$

where V is the specific volume in m^3/kg (ft^3/lbm).

For a perfect gas with $C^* = 0$ and any flow arrangement,

$$\left(\frac{1}{\varrho}\right)_m = \frac{\tilde{R}}{p_{ave}} T_{lm} \tag{28}$$

Here $\tilde{R}$ is the gas constant in $J\,kg^{-1}\,K^{-1}$, $p_{ave} = (p_i + p_o)/2$, and $T_{lm} = T_{const.} + \Delta T_{lm}$ where $T_{const.}$ is the mean average temperature of the fluid on the other side of the exchanger; the log-mean temperature difference ΔT_{lm} is defined in Table 5.

The core frictional pressure drop in Equation (26) may be approximated as

$$\Delta p \approx \frac{4 f L G^2}{2 g_c D_h} \left(\frac{1}{\varrho}\right)_m \tag{29}$$

5.4.2. Tube – Fin Exchangers

The pressure drop inside the tube is computed using Equation (26) with proper values of f (see the equations in Table 10) and K_c and K_e from [27], [39] for circular tubes.

For flat fins on an array of tubes (see Fig. 12), the components of the core pressure drop (such as those in Eq. (26)) are the same with the following exception: the core friction and momentum effect take place within the core with $G = W/A_o$, where A_o is the minimum free flow area within the core, and the entrance and exit losses occur at the leading and trailing edges of the core with the associated flow area A'_o so that

$$W = G A_o = G'_o A'_o \text{ or } G' \sigma' = G \sigma \tag{30}$$

where σ is the ratio of free flow area to frontal area at the fin leading edges.

The pressure drop for flow normal to a tube bank with flat fins is then given by

Table 8. Important dimensionless groups for internal flow forced convection heat transfer and flow friction, useful in heat exchanger design

Dimensionless groups	Definitions and working relationships	Physical meaning and comments
Reynolds number	$Re = \frac{\varrho v D_h}{\mu} = \frac{G D_h}{\mu}$	a flow modulus, proportional to the ratio of flow momentum rate ("inertia force") to viscous force
Fanning friction factor	$f = \frac{\tau_w}{(\varrho v^2/2 g_c)}$ $f = \Delta p^* \frac{r_h}{L} = \frac{\Delta p}{(\varrho v^2/2 g_c)} \frac{r_h}{L}$	the ratio of wall shear (skin frictional) stress to the flow kinetic energy per unit volume commonly used in heat transfer literature
Apparent Fanning friction factor	$f_{app} = \Delta p^* \frac{r_h}{L}$	includes the effects of skin friction and the change in the momentum rates in the entrance region (developing flows)
Incremental pressure drop number	$K(z) = (f_{app} - f_{fd}) \frac{L}{r_h}$ $K(\infty)$ = constant for $z \to \infty$	represents the excess dimensionless pressure drop in the entrance region over that for fully developed flow
Darcy friction factor	$f_D = 4f = \Delta p^* \frac{D_h}{L}$	four times the Fanning friction factor commonly used in fluid mechanics literature
Euler number	$Eu = \Delta p^* = \frac{\Delta p}{(\varrho v^2/2 g_c)}$	the pressure drop normalized with respect to the dynamic velocity head commonly used in the Soviet literature
Dimensionless axial distance for the fluid flow problem	$z^+ = \frac{z}{D_h Re}$	the ratio of the dimensionless axial distance (z/D_h) to the Reynolds number useful in the hydrodynamic entrance region
Nusselt number	$Nu = \frac{h}{k/D_h} = \frac{q'' D_h}{k(T_w - T_m)}$	the ratio of the convective conductance h to the pure molecular thermal conductance k/D_h
Stanton number	$St = \frac{h}{G c_p}$ $St = \frac{Nu}{Pe} = \frac{Nu}{Re Pr}$	the ratio of convection heat transfer (per unit duct surface area) to amount virtually transferable (per unit of flow cross-sectional area) no dependence upon any geometric characteristic dimension
Colburn factor	$j = St\, Pr^{2/3} = (Nu\, Pr^{-1/3})/Re$	a modified Stanton number to take into account the moderate variations in the Prandtl number for $0.5 \lesssim Pr \lesssim 10.0$ in turbulent flow
Prandtl number	$Pr = \frac{\nu}{\alpha} = \frac{\mu c_p}{k}$	a fluid property modulus representing the ratio of momentum diffusivity to thermal diffusivity of the fluid
Péclet number	$Pe = \frac{\varrho c_p v D_h}{k} = \frac{v D_h}{\alpha} = Re Pr$	proportional to the ratio of thermal energy convected to the fluid to thermal energy conducted axially within the fluid the inverse of Pe indicates relative importance of fluid axial heat conduction
Dimensionless axial distance for the heat transfer problem	$z^* = \frac{z}{D_h Pe} = \frac{z}{D_h Re Pr}$	useful in describing the thermal entrance region heat transfer results
Graetz number	$Gz = \frac{W c_p}{k L} = \frac{Pe P}{4L} = \frac{P}{4 D_h} \frac{1}{z^*}$ $Gz = \pi/(4z^*)$ for a circular tube	conventionally used in the chemical engineering literature related to z^* as shown when the flow length in Gz is treated as a length variable

$$\frac{\Delta p}{p_i} = \frac{G^2}{2 g_c} \frac{1}{p_i \varrho_i} \left[f \frac{L}{r_h} \varrho_i \left(\frac{1}{\varrho} \right)_m + 2 \left(\frac{\varrho_i}{\varrho_o} - 1 \right) \right] + \frac{G'^2}{2 g_c} \frac{1}{p_i \varrho_i} \left[\left(1 - \sigma'^2 + K_c \right) - \left(1 - \sigma'^2 - K_c \right) \frac{\varrho_i}{\varrho_o} \right] \quad (31)$$

For individually finned tubes shown in Figure 11, flow expansion and contraction take place along each tube row, and the magnitude is of the same order as that at the entrance and exit. Hence, the entrance and exit losses are generally lumped into the core friction factor. Equation (26) for individually finned tubes then reduces to

$$\frac{\Delta p}{p_i} = \frac{G^2}{2 g_c} \frac{1}{p_i \varrho_i} \left[f \frac{L}{r_h} \varrho_i \left(\frac{1}{\varrho} \right)_m + 2 \left(\frac{\varrho_i}{\varrho_0} - 1 \right) \right] \quad (32)$$

5.4.3. Regenerators

For regenerator matrices having cylindrical passages, the pressure drop is computed using Equation (26) with appropriate values of f, K_c, and K_e. For regenerator matrices made up of any porous material (such as checkerwork, wire mesh, spheres, copper wools, etc.), the pressure drop is calculated using Equation (32) in which the entrance and exit losses are included in the friction factor f.

5.4.4. Plate Heat Exchangers

Pressure drop in a plate heat exchanger consists of three components: (1) pressure drop associated with the inlet and outlet manifolds and ports, (2) pressure drop within the core (plate

passages), and (3) pressure drop due to the elevation change. The pressure drop in the manifolds and ports should be kept as low as possible (generally $< 10\,\%$, but may be as high as $25-30\,\%$ in some designs). Empirically, it is calculated as approximately 1.5 times the inlet velocity head per pass. Since the entrance and exit losses in the core (plate passages) cannot be determined experimentally, they are included in the friction factor for the given plate geometry. The pressure drop (rise) caused by the elevation change for liquids is given by Equation (25). Hence, the pressure drop on one fluid side in a plate heat exchanger is given by

$$\Delta p = \frac{1.5G^2N}{2g_c\varrho_i} + \frac{4fLG^2}{2g_cD_e}\left(\frac{1}{\varrho}\right)_m + \left(\frac{1}{\varrho_o} - \frac{1}{\varrho_i}\right)\frac{G^2}{g_c} \pm \frac{\varrho_m gL}{g_c} \tag{33}$$

where N is the number of passes on the given fluid side, and D_e is the equivalent diameter of flow passages (usually twice the plate spacing).

6. Single-Phase Heat-Transfer and Pressure-Drop Correlations

6.1. Basic Concepts and Dimensionless Groups

Heat-transfer characteristics of an exchanger surface are presented in terms of the Nusselt number, Stanton number, or Colburn factor vs. the Reynolds number, z^*, or Graetz number. Flow friction characteristics are presented in terms of the Fanning friction factor vs. Re or z^+. These and other important dimensionless groups used in presenting and correlating internal flow forced convection heat transfer are summarized in Table 8 with their definitions and physical meanings. Where applicable, the hydraulic diameter D_h is used as a characteristic dimension in all dimensionless groups. A number of different definitions are used in literature for some of the dimensionless groups; the user should pay particular attention to the specific definitions used in any research paper before using specific results. This is particularly true for the Nusselt number where many different temperature differences are used in the definition of h, and for f, Re, and other dimensionless groups having characteristic dimensions different from D_h. As an example of these correlating groups, basic heat-transfer and flow friction characteristics for air flow in a long circular tube are presented in Figure 33. There is a parallel behavior of j vs. Re and f vs. Re curves, but no such parallelism exists between Nu and f vs. Re curves. The parallel behavior of j and f vs. Re is useful for: (1) identifying erroneous test data for some specific surfaces for which parallel behavior is expected but indicated otherwise by test results; (2) identifying specific flow phenomena in which the friction behavior is different from the heat transfer behavior (such as flow over rough surfaces in turbulent flow); and (3) predicting the f factors for an unknown surface when the j factors are known by some predictive method. It should be remembered that j vs. Re can readity be converted to Nu vs. Re curves or vice versa because $j = (Nu\,Pr^{-1/3})/Re$ by definition.

Figure 33 shows three flow regimes: laminar, transition, and turbulent. This is characteristic of fully developed flow in continuous flow passage geometries such as a long circular tube, triangular tube, etc. Generally, the compact interrupted surfaces do not have a sharp "dip" in the transition region ($Re \sim 1500-10\,000$) as shown for the circular tube.

6.2. Theoretical Solutions and Correlations for Simple Geometries

Flow passages in most compact heat exchangers are complex with frequent boundary layer interruptions; some heat exchangers (particularly the tube side of shell-and-tube exchangers and highly compact regenerators) have continuous flow passages. The velocity and temperature profiles across the flow cross section are generally fully developed in the continuous flow passages, whereas they develop at each boundary layer interruption in an interrupted surface. The heat-transfer and flow friction characteristics are generally different for fully developed flows and developing flows. Analytical results for developed and developing flows for simple flow passage geometries follow. For complex surface geometries, the basic surface characteristics are primarily obtained experimentally [27]; the pertinent correlations are presented in Section 6.3.

Figure 33. Basic heat transfer and flow friction characteristics for air flow through a long circular tube

Three important thermal boundary conditions for heat exchangers are Ⓣ, Ⓗ1, Ⓗ2. The Ⓣ boundary condition refers to constant wall temperature, both axially and peripherally throughout the passage length. The wall heat-transfer rate is constant in the axial direction while the wall temperature at any cross section is constant in the peripheral direction for the Ⓗ1 boundary condition. The wall heat-transfer rate is constant in the axial direction as well as in the peripheral direction for the Ⓗ2 boundary condition. The Ⓗ1 boundary condition is realized for highly conductive materials where the temperature gradients in the peripheral direction are at a minimum; the Ⓗ2 boundary condition is realized for very poorly conducting materials for which temperature gradients exist in the peripheral direction. For intermediate thermal conductivity values, the boundary condition will be in between that of Ⓗ1 and Ⓗ2. In general, $Nu_{\mathrm{H1}} > Nu_{\mathrm{T}}$, $Nu_{\mathrm{H1}} \geq Nu_{\mathrm{H2}}$, and $Nu_{\mathrm{H2}} \lessgtr Nu_{\mathrm{T}}$.

The heat-transfer rate in laminar duct flow is very sensitive to the thermal boundary condition. Hence, it is essential to carefully identify the thermal boundary condition in laminar flow. The heat-transfer rate in turbulent duct flow is insensitive to the thermal boundary condition for most common fluids ($Pr \gtrsim 0.7$) except for liquid metals ($Pr < 0.03$). Hence, there is generally no need to identify the thermal boundary condition in turbulent flow for all fluids except liquid metals.

6.2.1. Fully Developed Flows

Laminar Flow. Nusselt numbers for fully developed laminar flow are constant, but depend on the flow passage geometry and thermal boundary conditions. The product of the Fanning friction factor and the Reynolds number is also constant, but is dependent on the flow passage geometry. Fully developed laminar flow problems are analyzed extensively in [40], [41]; most of the analytical solutions are also presented in closed-form equations in [41]. Solutions for some technically important flow passages are presented in Table 9.

A number of observations may be made from the results of Table 9 for fully developed laminar flow through straight constant cross-sectional ducts:

1) Flow passage geometry strongly influences the values of Nu and fRe. Rectangular flow passages which approach a small aspect ratio exhibit the highest Nu and fRe.
2) The thermal boundary conditions Ⓗ1, Ⓗ2, and Ⓣ have a strong influence on the Nusselt number. Depending on the flow geometry, j factors for the Ⓗ1 boundary condition may be of the order of 50 % greater than that for the Ⓗ2 boundary condition, and about 20 % greater than that for the Ⓣ boundary condition.

Table 9. Solutions for heat transfer and friction for fully developed laminar flow through specified ducts [40]

Geometry ($L/D_h > 100$)		Nu_{H1}	Nu_{H2}	Nu_T	fRe	$\frac{j_{H1}}{f}$ [a]	$K(\infty)$ [b]	L_{hy}^{+} [c]
	$\frac{2b}{2a} = \frac{\sqrt{3}}{2}$	3.014	1.474	2.39	12.630	0.269	1.739	0.04
	$\frac{2b}{2a} = \frac{\sqrt{3}}{2}$	3.111	1.892	2.47	13.333	0.263	1.818	0.04
	$\frac{2b}{2a} = 1$	3.608	3.091	2.976	14.227	0.286	1.433	0.090
		4.002	3.862	3.34	15.054	0.299	1.335	0.086
	$\frac{2b}{2a} = \frac{1}{2}$	4.123	3.017	3.391	15.548	0.299	1.281	0.085
		4.364	4.364	3.657	16.000	0.307	1.25	0.056
	$\frac{2b}{2a} = \frac{1}{4}$	5.331	2.94	4.439	18.233	0.329	1.001	0.078
	$\frac{2b}{2a} = \frac{1}{6}$	6.049	2.93	5.137	19.702	0.346	0.885	0.070
	$\frac{2b}{2a} = \frac{1}{8}$	6.490	2.94	5.597	20.585	0.355	0.825	0.063
	$\frac{2b}{2a} = 0$	8.235	8.235	7.541	24.000	0.386	0.674	0.011

[a] $j_{H1}/f = Nu_{H1}\, Pr^{-1/3}/(fRe)$ with $Pr = 0.7$. Similarly, values of j_{H2}/f and j_T/f may be computed.
[b] $K(\infty)$ for sine and equilateral triangular channels may be too high [40]; $K(\infty)$ for some rectangular and hexagonal channels is interpolated based on the recommended values in Ref. [40].
[c] L_{hy}^{+} for sine and equilateral triangular channels is too low [40], so use with caution. L_{hy}^{+} for rectangular channels is based on the faired curve drawn through the recommended value in [40]. L_{hy}^{+} for a hexagonal channel is an interpolated value.

3) As $Nu = h\,D_h/k$, a constant Nu implies a convective coefficient h independent of the flow velocity.
4) An increase in h is best achieved by reducing D_h, or by a change in the type of geometry for a specified fluid.
5) Since $fRe = \text{const.}$, $f \propto 1/Re \propto 1/v$. In this case, it can be shown that $\Delta p \propto v$.

Transition Flow. The lower limit of the critical Reynolds number Re_{cr} at which transition to turbulent flow occurs in smooth passages is a function of the passage inlet configuration. With a sharp square inlet configuration, Re_{cr} is ca. 10 – 15 % lower than that with a rounded inlet configuration. The lower limits of Re_{cr} for various passages with a sharp square inlet configuration vary from about 2000 to 3100 [42]. The upper

limit of Re_{cr} may be taken as 10^4 for most practical purposes.

BHATTI and SHAH [42] developed a Fanning friction factor formula for laminar, transition, and turbulent flow regimes in a circular passage; this is presented in Table 10. The transition flow f data for noncircular passages are rather sparse; the equation for the circular tube in Table 10 may be used to obtain fair estimates of f for noncircular flow passages (having no sharp corners) using the hydraulic diameter as the characteristic dimension.

The heat transfer results for transition flow are rather uncertain in view of the large number of parameters necessary to characterize the heat-affected transition flow. The following Nusselt number correlation [42] for $0 < Pr < \infty$ and $2100 \leq Re \leq 10^6$ spanning laminar, transition, and turbulent flow regimes in a circular passage, is recommended for calculating the transition flow $j = Nu\,Pr^{-1/3}/Re$:

$$Nu = \left\{ Nu_{\mathrm{L}}^{10} + \left[\frac{\exp\left[(2200 - Re)/365\right]}{Nu_{\mathrm{L}}^{2}} + \frac{1}{Nu_{\mathrm{T}}^{2}} \right]^{-5} \right\}^{1/10} \tag{34}$$

where

$$Nu_{\mathrm{L}} = \begin{cases} 3.657 & \text{for (T) boundary condition} \\ 4.364 & \text{for (H) boundary condition} \end{cases} \tag{35}$$

$$Nu_{\mathrm{T}} = Nu_0 + \frac{0.079\,(f/2)^{1/2}\,RePr}{\left(1 + Pr^{4/5}\right)^{5/6}} \tag{36}$$

$$Nu_{\mathrm{o}} = \begin{cases} 4.8 & \text{for (T) boundary condition} \\ 6.3 & \text{for (H) boundary condition} \end{cases} \tag{37}$$

Since no j factors are available for transition flow for noncircular passages, Equations (34) – (37) may be used to obtain fair estimates of j for noncircular passages (having no sharp corners) using the hydraulic diameter as the characteristic dimension.

Turbulent Flow. A compendium of available f and Nu correlations for circular and noncircular flow passages are presented in [42]. Table 10 is condensed from [42] summarizing the most accurate f and Nu correlations for smooth circular and noncircular passages.

It is generally accepted that the hydraulic diameter correlates Nu and f for fully developed turbulent flow in circular and noncircular ducts. This is true for the results accurate to within $\pm 15\,\%$ for most noncircular ducts. Exceptions are for those having sharp or acute-angled corners in the flow passage or concentric annuli with inner wall heating. In these cases, Nu and f could be lower than 15 % compared to the circular tube values. Table 10 can be used for more accurate correlations of Nu and f for noncircular ducts.

Roughness on the surface causes local flow separation and reattachment. This generally results in an increase in the friction factor as well as the heat-transfer coefficient. A roughness element has no effect on laminar flow, unless the height of the roughness element is not negligible compared to the flow cross section size. However, it exerts a strong influence on turbulent flow. Specific correlations to account for the influence of surface roughness are presented in [42], [43].

6.2.2. Hydrodynamically Developing Flows

Laminar Flow. Based on the solutions for laminar boundary layer development over a flat plate and fully developed flow in circular and some noncircular ducts, $f_{\mathrm{app}}Re$ can be correlated by the following equation:

$$f_{\mathrm{app}}Re = 3.44\left(z^{+}\right)^{-0.5} + \frac{K(\infty)/\left(4z^{+}\right) + fRe - 3.44\left(z^{+}\right)^{-0.5}}{1 + c'\left(z^{+}\right)^{-2}} \tag{38}$$

where $K(\infty)$, fRe, and c' are given in Table 11.

Table 10. Fully developed turbulent flow friction factors and Nusselt numbers ($Pr > 0.5$) for technically important smooth-walled ducts [41]

Duct geometry and characteristic dimension	Recommended correlations[a]
 Circular $D_h = 2a$	friction factor correlation for $2300 \le Re \le 10^7$ [41]: $f = A + \frac{B}{Re^{1/m}}$ where $A = 0.0054$, $B = 2.3 \times 10^{-8}$, $m = -2/3$ for $2100 \le Re \le 4000$ and $A = 1.28 \times 10^{-3}$, $B = 0.1143$, $m = 3.2154$ for $4000 \le Re \le 10^7$ [41]. Nusselt number correlation by Gnielinski for $2300 \le Re \le 5 \times 10^6$: $Nu = \frac{(f/2)(Re - 1000)\,Pr}{1 + 12.7\,(f/2)^{1/2}\,(Pr^{2/3} - 1)}$
 Flat $D_h = 4b$	use circular duct f and Nu correlations. Predicted f are up to 12.5% lower and predicted Nu are within $\pm 9\%$ of the most reliable experimental results.
 Rectangular $D_h = \frac{4ab}{a+b}$, $\alpha^* = \frac{2b}{2a}$ $\frac{D_l}{D_h} = \frac{2}{3} + \frac{11}{24}\alpha^*(2 - \alpha^*)$	f factors: (1) substitute D_l for D_h in the circular duct correlation, and calculate f from the resulting equation. (2) Alternatively, calculate f from $f = (1.0875 - 0.1125\,\alpha^*)\,f_c$ where f_c is the friction factor for the circular duct using D_h. In both cases, predicted f factors are within $\pm 5\%$ of the experimental results. Nusselt numbers: (1) With uniform heating at four walls, use ciruclar duct Nu correlation for an accuracy of $\pm 9\%$ for $0.5 \le Pr \le 100$ and $10^4 \le Re \le 10^6$. (2) With equal heating at two long walls, use circular duct correlation for an accuracy of $\pm 10\%$ for $0.5 < Pr \le 10$ and $10^4 \le Re \le 10^5$. (3) With heating at one long wall only, use circular duct correlation to get approximate Nu values for $0.5 < Pr < 10$ and $10^4 \le Re \le 10^6$. These calculated values may be up to 20% higher than the actual experimental values.
 Equilateral triangular $D_h = 2\sqrt{3}\,a = 4b/3$ $D_l = \sqrt{3}\,a = 2b/3\sqrt{3}$	use circular duct f and Nu correlations with D_h replaced by D_l. Predicted f are within $+3\%$ and -11% and predicted Nu within $+9\%$ of the experimental values.
 Isosceles triangular $D_h = \frac{4ab}{a + \sqrt{a^2 + b^2}}$ $\frac{D_g}{D_h} = \frac{1}{2\pi}\left[3 \ln \cot \frac{\theta}{2} + 2 \ln \tan \frac{\varphi}{2} - \ln \tan \frac{\theta}{2}\right]$ where $\theta = (90° - \varphi)/2$	for $0 < 2\varphi < 60°$, use circular duct f and Nu correlations with D_h replaced by D_g; for $2\varphi = 60°$, replace D_h by D_l (see above); and for $60° < 2\varphi \le 90°$ use circular duct correlations directly with D_h. Predicted f and Nu are within $+9\%$ and -11% of the experimental values. No recommentations can be made for $2\varphi > 90°$ due to lack of the experimental data.

Table 10. Continued

Concentric annular

$D_h = 2(r_o - r_i)$,

$r^* = \frac{r_i}{r_o}$

$\frac{D_1}{D_h} = \frac{1 + r^{*2} + (1 - r^{*2})/\ln r^*}{(1 - r^*)^2}$

f Factors: (1) Substitute D_1 for D_h in the circular duct correlation, and calculate f from the resulting equation. (2) Alternatively, calculate f from $f = (1 + 0.0925\, r^*)\, f_c$ where f_c is the friction factor for the circular duct using D_h. In both cases, predicted f factors are within $\pm 5\%$ of the experimental results.

Nusselt Numbers: In all the following recommendations, use D_h with a wetted perimeter in Nu and Re: (1) Nu at the outer wall can be determined from the circular duct correlation within the accuracy of about $\pm 10\%$ regardless of the condition at the inner wall. (2) Nu at the inner wall cannot be determined accurately regardless of the heating/cooling condition at the outer wall.

[a] The friction factor and Nusselt number corrlations for the circular duct are the most reliable and agree with a large amount of the experimental data within $\pm 2\%$ and $\pm 10\%$ respectively. The correlations for all other duct geometries are not as good as those for the circular duct on an absolute basis.

Table 11. $K(\infty)$, fRe, and c' for use in Equation (38)

	$K(\infty)$	fRe	$10^3\, c'$	% error
α^*	*Rectangular ducts*			
1.00	1.43	14.277	0.29	± 2.3
0.50	1.28	15.548	0.21	± 1.9
0.20	0.931	19.071	0.076	± 1.7
0.00	0.674	24.000	0.029	± 2.4

r^*	*Concentric annular ducts*			
0	1.25	16.000	0.212	± 1.9
0.05	0.830	21.567	0.050	± 2.0
0.10	0.784	22.343	0.043	± 1.9
0.50	0.688	23.813	0.032	± 2.2
0.75	0.678	23.967	0.030	± 2.1
1.00	0.674	24.000	0.029	± 2.4

The $f_{\mathrm{app}}\, Re$ factors for four passage geometries calculated from the foregoing formulas are compared in [40], [41].

Turbulent Flow. $f_{\mathrm{app}}\, Re$ for turbulent flow depends on Re in addition to z^+. A closed-form formula for $f_{\mathrm{app}}\, Re$ is given in [42], [43] for developing turbulent flow.

The hydrodynamic entrance length for developing laminar and turbulent flow are given by [43]:

$$L_{\mathrm{hy}}/D_{\mathrm{h}} = 0.056 Re$$

$$\text{for laminar flow } (Re \leq 2100) \tag{39}$$

$$L_{\mathrm{hy}}/D_{\mathrm{h}} = 1.359 Re^{1/4}$$

$$\text{for turbulent flow } \left(Re \geq 10^4\right) \tag{40}$$

6.2.3. Thermally Developing Flows

Laminar Flow. Thermal entry length solutions with developed velocity profiles are summarized in [40], [41] for a large number of practically important flow passage geometries with extensive comparisons.

SHAH and LONDON [40] proposed the following correlations for thermal entrance solutions for circular and noncircular ducts having laminar developed velocity profiles and developing temperature profiles.

$$Nu_{\mathrm{z,T}} = 0.427\, (f\, Re)^{1/3}\, (z^*)^{-1/3} \tag{41}$$

$$Nu_{\mathrm{m,T}} = 0.641\, (f\, Re)^{1/3}\, (z^*)^{-1/3} \tag{42}$$

$$Nu_{\mathrm{z,H1}} = 0.517\, (f\, Re)^{1/3}\, (z^*)^{-1/3} \tag{43}$$

$$Nu_{\mathrm{m,H1}} = 0.775\, (f\, Re)^{1/3}\, (z^*)^{-1/3} \tag{44}$$

where f is the Fanning friction factor for fully developed flow, Re is the Reynolds number, and $z^* = z/(D_{\mathrm{h}} Re\, Pr)$. For interrupted surfaces,

$z = l_{\mathrm{ef}}$. Equations (41) – (44) are recommended for $z^* < 0.001$.

The following observations may be made from Equations (41) – (44) and solutions for laminar flow surfaces having developing temperature profiles given in [40], [41].

1) The influence of thermal boundary conditions on the convective behavior appears to be of the same order as that for fully developed flow.
2) Since $Nu \propto (z^*)^{-1/3} = [z/(D_{\mathrm{h}} Re\, Pr)]^{-1/3}$, then $Nu \propto Re^{1/3} \propto v^{1/3}$. Therefore h varies as $v^{1/3}$.
3) Since the velocity profiles is considered fully developed, $\Delta p \propto v_{\mathrm{m}}$ as noted earlier.
4) The influence of the duct shape on thermally developed Nu is not as great as that for the fully developed Nu.

Figure 34. The ratio of laminar developing to developed flow Nu for different ducts; the velocity profile is developed for both Nu's
a) Equilateral triangular; b) Square duct; c) $\alpha^* = 1/2$ Rectangular duct; d) Circular duct; e) $\alpha^* = 1/4$ Rect. duct; f) $\alpha^* = 1/6$ Rect. duct; g) Parallel plates

The theoretical ratio Nu_{m}/Nu_{fd} is shown in Figure 34 for several passage geometries having constant wall temperature boundary conditions. Several observations may be made from this figure:

1) The Nusselt numbers in the entrance region and hence the heat transfer coefficients could be 2 – 3 times higher than the fully developed values depending on the interruption length $l^*_{\mathrm{ef}} = z^*$.
2) At $z^* \approx 0.1$, the local Nusselt number approaches the fully developed value, but the value of the mean Nusselt number can be significantly higher for a channel of length $l^*_{\mathrm{ef}} = z^* = 0.1$.
3) The order of increasing $\mathrm{Nu}_{\mathrm{m}}/Nu_{\mathrm{fd}}$ as a function of channel shape at a given z^* is the opposite of Nu_{fd} in Table 9. For a highly interrupted surface, a basic inferior passage geometry for fully developed flow (such as triangular) will not be penalized in terms of low Nu or low h in developing flow.
4) A higher value of $Nu_{\mathrm{m}}/Nu_{\mathrm{fd}}$ at $z^* = 0.1$ means that the flow channel has a longer entrance region.

Turbulent Flow. The thermal entry length solutions for smooth ducts of several cross-sectional geometries have been summarized [42]. As for laminar flow, the Nusselt numbers in the thermal region are higher than those in the fully developed region. However, unlike laminar flow, $Nu_{z,\mathrm{T}}$ and $Nu_{z,\mathrm{H1}}$ are very nearly the same for turbulent flow. The local and mean Nusselt numbers for a circular tube with Ⓣ and Ⓗ boundary conditions are [42]:

$$\frac{Nu_x}{Nu_\infty} = 1 + \frac{c}{10\,(z/D_{\mathrm{h}})}\,; \quad \frac{Nu_{\mathrm{m}}}{Nu_\infty} = 1 + \frac{c}{z/D_{\mathrm{h}}} \tag{45}$$

where Nu_∞ stands for the fully developed Nu_{T} or Nu_{H} derived from the formulas in Table 10, and

$$c = \frac{(z/D_{\mathrm{h}})^{0.1}}{Pr^{1/6}} \left(0.68 + \frac{3000}{Re^{0.81}}\right) \tag{46}$$

This correlation is valid for $z/D_{\mathrm{h}} > 3$, $3500 < Re < 10^5$, and $0.7 < Pr < 75$. It agrees within $\pm 12\,\%$ with the experimental measurements for $Pr = 0.7$.

6.2.4. Simultaneously Developing Flows

Laminar Flow. In simultaneously developing flow, both the velocity and temperature profiles develop in the entrance region. The available analytical solutions are summarized in [40], [41]. The theoretical entrance region Nusselt numbers for simultaneously developing flow are higher than those for thermally developing and hydrodynamically developed flow. These theoretical solutions do not take into account the wake effect or secondary flow effect which are present in flow over interrupted heat-transfer

surfaces. Experimental data indicate that the interrupted heat-transfer surfaces do not achieve higher heat-transfer coefficients predicted for the simultaneously developing flows. The results for thermally developing flows (and developed velocity profiles) are in better agreement with the experimental data for interrupted surfaces and hence are recommended for design purpose.

Turbulent Flow. The Nusselt numbers for simultaneously developing turbulent flow are practically the same as the Nusselt numbers for the thermally developing turbulent flow [42]. However, the Nusselt numbers for simultaneously developing flow are sensitive to the passage inlet configuration.

Table 12 summarizes the dependence of Δp and h on v for developed and developing laminar and turbulent flows. Although these results are for the circular tube, the general functional relationship should be valid for noncircular ducts as a first approximation.

Table 12. Dependence of pressure drop and heat-transfer coefficient on the flow mean velocity for internal flow in a constant cross-sectional duct

Flow type	$\Delta p \propto v^{\mathrm{p}}$		$h \propto v^{\mathrm{q}}$	
	Laminar	Turbulent	Laminar	Turbulent
Fully developed	v	$v^{1.8}$	v^{0}	$v^{0.8}$
Hydrodynamically developing	$v^{1.5}$	$v^{1.8}$	–	–
Thermally developing	v	$v^{1.8}$	$v^{1/3}$	$v^{0.8}$
Simultaneously developing	$v^{1.5}$	$v^{1.8}$	$v^{1/2}$	$v^{0.8}$

6.3. Empirical Correlations for Complex Geometries

The results presented in the preceding sections are for well-defined flow passages with unobstructed constant area and essentially unidirectional flow. The flows encountered in actual heat exchangers are very complex, involving such processes as separation, reattachment, recirculation (i.e., backflow), and vortex action. These flow processes significantly influence the hydraulic and thermal performance of a heat exchanger surface. However, the detailed manner in which these processes influence j and f is difficult to treat analytically. Hence, f and j factors for complex heat exchanger surfaces have to be determined experimentally.

There is only a limited amount of information in the literature available for j and f data for complex surfaces used in present-day commercial devices. Such information is frequently retained as business-sensitive proprietary information by heat exchanger manufacturers. The primary source of j and f data for complex surfaces is found in [39]: this literature source contains information for over 100 surfaces, many of which, however, are manufactured with technologies that are now obsolete.

Correlations have been developed in literature for tubular, plate, and extended surface heat exchangers which are summarized next.

6.3.1. Tubular Exchangers

The principal geometric parameters that influence fluid flow and heat transfer of a tube bank are: (1) tube diameter, (2) longitudinal and transverse tube pitches, (3) number of tube rows, (4) tube arrangement, and (5) fin geometry and type, if any. Figure 25 shows the two most common tube arrangements–the inline and staggered arrangements in four-tube layouts.

Flow conditions within the tube bank are dominated by boundary layer separation effects and wake interactions; therefore, the heat-transfer coefficients and friction factors associated with a tube are determined by the tube location in the bank. Due to the turbulence caused by the first few rows, the inner rows of a bare tube bank will have higher heat-transfer coefficients and friction factors. For bare or finned tube banks, the heat-transfer coefficient will decrease with an increasing number of tube rows in an inline bank due to the flow bypass effect; it will, however, increase with the number of tube rows in a staggered bank, due to the shedding of turbulent eddies, thereby providing good fluid mixing for downstream tube rows. In bare tube banks, the dimensionless heat-transfer coefficients and friction factors approach asymptotic values beyond about 16 tube rows, and for finned tube banks beyond about 4 tube rows [44].

Bare Tube Banks. Many correlations are published for friction factors and Nusselt numbers for bare tube banks. One of the most com-

prehensive correlations by ZUKAUSKAS [44] is now summarized. He provided the modified friction factor f'/χ vs. Re_d correlations in graphical form for (a) inline arrangement (90° tube layout), and (b) staggered arrangement (30° tube layout) as shown in Figures 35 and 36 for specific values of X_t and X_l. For other inline and staggered tube arrangements, a correction factor χ is obtained from the insets of these figures. Here f' is defined by

$$\Delta p = 4f' \frac{G^2}{2g_c \varrho} N_r \tag{47}$$

where f' is an empirical Fanning friction factor per tube row, N_r is the number of tube rows in flow direction, and G is the mass velocity based on the minimum free flow area.

The Nusselt number for flow normal to the tube banks is also dependent upon the tube arrangements, tube pitch-to-diameter ratio, number of tube rows, Reynolds number, and Prandtl number. ZUKAUSKAS [44] also presented correlations for the mean Nusselt number $Nu_m = h_m d_o/k$ as

$$Nu_m = F_c \, (Nu_m)_{16\text{rows}} \tag{48}$$

Values of Nu_m for 16 and more tube rows are presented in Table 13 for inline (90° tube layout) and staggered (30° tube layout) arrangements. For all expressions in Table 13, fluid properties in Nu, Re_d, and Pr are evaluated at the bulk mean temperature and for Pr_w at the wall temperature. The tube row correction factor F_c is presented in Figure 37 as a function of the number of tube rows N_r for inline and staggered arrangements.

Table 13. Mean Nusselt number correlations for inline and staggered tube bundles [44]

Range of Re	Recommended correlations
	Inline tube bundles
$10^0 - 10^2$	$Nu = 0.9\, Re^{0.4}\, Pr^{0.36}\, (Pr/Pr_w)^{0.25}$
$10^2 - 10^3$	$Nu = 0.52\, Re^{0.5}\, Pr^{0.36}\, (Pr/Pr_w)^{0.25}$
$10^3 - 2\times10^5$	$Nu = 0.27\, Re^{0.63}\, \mathrm{Pr}^{0.36}\, (Pr/Pr_w)^{0.25}$
$2\times10^5 - 2\times10^6$	$Nu = 0.033\, Re^{0.8}\, Pr^{0.4}\, (Pr/Pr_w)^{0.25}$
	Staggered tube bundles
$10^0 - 5\times10^2$	$Nu = 1.04\, Re^{0.4}\, Pr^{0.36}\, (Pr/Pr_w)^{0.25}$
$5\times10^2 - 10^3$	$Nu = 0.71\, Re^{0.5}\, Pr^{0.36}\, (Pr/Pr_w)^{0.25}$
$10^3 - 2\times10^5$	$Nu = 0.35\, (X_t/X_l)^{0.2}\, Re^{0.6} \cdot Pr^{0.36}\, (Pr/Pr_w)^{0.25}$
$2\times10^5 - 2\times10^6$	$Nu = 0.031\, (X_t/X_l)^{0.2}\, Re^{0.8} \cdot Pr^{0.36}\, (PrPr_w)^{0.25}$

Figure 37. A correction factor to account for the tube-row effect for heat transfer for flow normal to bare tube banks [44]

Finned Tube Banks. Heat-transfer and flow friction correlations are summarized separately for two types of tube – fin surfaces: individually finned tubes, and flat fins on a tube array.

A staggered tube arrangement is preferred for multirow finned tube banks. The heat-transfer coefficient of an inline finned tube bank is substantially lower than that for a staggered arrangement because of the flow bypass through the gap if the fins are not touching. No correlations are available for inline tube banks. Therefore, staggered tube arrangements are dealt with in this section.

Individually Finned Circular Tubes. These fins are quite commonly used on the gas side. Many different interrupted circular fins have been used by industry. However, the data are mostly proprietary. Multiple regression-type correlations are only published for the plain fins, as follows.

For heat transfer, BRIGGS and YOUNG [45] recommend the following correlation for equilateral triangular staggered tube banks.

$$j = 0.134\, Re_d^{-0.319} \left(s'/l_f\right)^{0.2} \left(s'/\delta_f\right)^{0.11} \tag{49}$$

where $s' = (1/N_f) - \delta_f$ is the distance between adjacent fins. Equation (49) is valid for the following ranges: $1100 \le Re_d \le 18\,000$, $0.13 \le s'/l_f \le 0.63$, $1.01 \le s'/\delta_f \le 6.62$, $0.09 \le l_f/d_o \le 0.69$, $0.011 \le \delta_f/d_o \le 0.15$, $1.65 \le X_t/d_o \le 8.23$, fin root diameter d_o between 11.1 and 40.9 mm, and fin density N_f between 246 and 768 fins/m.

For isothermal pressure drops, based on data for an equilateral triangular and two isosceles triangular staggered tube banks, the following correlation is recommended [46]:

Figure 35. Friction factors for inline tube arrangement [44]
a) $X_l = 1.25$; b) $X_l = 1.5$; c) $X_l = 2.0$; d) $X_l = 2.5$

Figure 36. Friction factors for staggered tube arrangement [44]
a) $X_l = 1.25$; b) $X_l = 1.5$; c) $X_l = 2.0$; d) $X_l = 2.5$; $X_t^* = X_t/d_o$

$$f' = 9.465 Re_d^{-0.316} (X_t/d_o)^{-0.927} (X_t/X_d)^{0.515} \tag{50}$$

where $X_d = (X_t^2 + X_l^2)^{1/2}$ is the diagonal pitch. The correlation is valid for the following ranges: $2000 \le Re_d \le 50\,000$, $0.15 \le s'/l_f \le 0.19$, $3.75 \le s'/\delta_f \le 6.03$, $0.35 \le l_f/d_o \le 0.56$, $0.011 \le \delta_f/d_o \le 0.025$, $1.86 \le X_t/d_o \le 4.60$, $18.6 \le d_o \le 40.9$ mm, and $311 \le N_f \le 431$ fins/m.

Alternative correlations for (high) finned tubes are given in [44].

Extensive work has been reported on low-finned tubes and is assessed in [47–49]. A simple but accurate correlation for heat transfer is given in [48] as

$$j = 0.255 Re_d^{-0.3} (d_e/s')^{-0.3} \tag{51}$$

A more accurate correlation for heat transfer is given in [47]. Based on the comparison of existing data in literature and various correlations, Chai [49] has arrived at the best correlation for friction factors:

$$f' = 1.748 Re_d^{-0.233} \left(\frac{l_f}{s'}\right)^{0.552} \cdot \left(\frac{d_o}{X_t}\right)^{0.599} \left(\frac{d_o}{X_l}\right)^{0.1738} \tag{52}$$

This correlation is valid for $895 \le Re_d \le 713\,000$, $20 \le \theta \le 40$, $X_t/d_o < 4$, $N_r \ge 4$, and θ is the tube layout angle. It predicts 89 literature data points within a mean absolute error of 6 %; the range of actual error is from − 16.7 to + 19.9 %.

The design data for a number of augmented circular fins have been summarized in [50].

Flat Fins on a Tube Array. GRAY and WEBB [51] recommend the following heat-transfer correlation for plain flat fins on staggered tube arrays valid for four or more tube rows.

$$j_4 = 0.14 Re_{\mathrm{d}}^{-0.328} \left(\frac{X_{\mathrm{t}}}{X_{\mathrm{l}}}\right)^{-0.50} \left(\frac{s}{d_{\mathrm{o}}}\right)^{0.031} \tag{53}$$

For the number of rows N_{r} from 1 to 3, the j factor is lower and is given by

$$\frac{j_{N_{\mathrm{r}}}}{j_4} = 0.991 \left[2.24 Re_{\mathrm{d}}^{-0.092} \left(\frac{N_{\mathrm{r}}}{4}\right)^{-0.031}\right]^n \tag{54}$$

where $n = 0.607\,(4 - N_{\mathrm{r}})$.

Equations (53) and (54) correlated 89 % of the test data for 16 heat exchangers within $\pm 10\,\%$.

Pressure drop on the fin side in a tube and flat fin exchanger (staggered layout) consists of pressure drop associated with fins and that associated with tubes. Hence, GRAY and WEBB [51] defined the tube side effective friction factor f' as a sum of the individual friction factors associated with the fin and the tube, weighted with respect to surface areas

$$f' = f'_{\mathrm{f}} \frac{A_{\mathrm{f}}}{A} + f'_{\mathrm{t}} \left(1 - \frac{A_{\mathrm{f}}}{A}\right) \left(1 - \frac{\delta_{\mathrm{f}}}{s}\right) \tag{55}$$

Here f'_{f} is the friction factor associated with fins and f'_{t} is the friction factor associated with bare bank of tubes. While f'_{t} is obtained from the Zukauskas correlation (see Fig. 36), f'_{f} was correlated as

$$f'_{\mathrm{f}} = 0.508 Re_{\mathrm{d}}^{-0.521} \left(\frac{X_{\mathrm{t}}}{d_0}\right)^{1.318} \tag{56}$$

Equation (55) correlated 90 % of the data for 19 heat exchangers within $\pm 20\,\%$. The range of dimensionless variables of Equations (53) – (55) are: $500 < Re_{\mathrm{d}} < 24\,700$, $1.97 < X_{\mathrm{t}}/d_{\mathrm{o}} < 2.55$, $1.7 < X_{\mathrm{l}}/d_{\mathrm{o}} < 2.58$, and $0.08 < s'/d_{\mathrm{o}} < 0.64$.

Published data on other flat interrupted fins on a staggered tube array are presented in [39], [50].

6.3.2. Plate Exchangers

Most heat-transfer and flow friction characteristics (correlations) for various plate designs are proprietary; very little useful information has been published in the open literature. A comprehensive survey of correlations which are available in the open literature is given in [52].

Heat-Transfer Correlations. Forced convection heat-transfer coefficients for fully developed turbulent liquid flow in plate exchangers are usually correlated as

$$Nu = c_1 Re^{c_2} Pr^{c_3} \left(\frac{\mu_{\mathrm{m}}}{\mu_{\mathrm{w}}}\right)^n \tag{57}$$

where the empirical constants c_1 and c_2 are dependent upon the plate pattern and geometrical parameters. Typical values for transition and turbulent flow regimes are [53]:

$$c_1 = 0.15 - 0.40 \quad c_2 = 0.65 - 0.85$$
$$c_3 = 0.30 - 0.45 \quad n = 0.05 - 0.20 \tag{58}$$

Since liquids have $Pr > 1$ and are exclusively used in plate exchangers, the Nusselt number of Equation (57) is independent of thermal boundary conditions in turbulent flow.

In the laminar regime, Lévêque's correlation has been proposed for plate exchangers [54]

$$Nu = c_4 \left(z^*\right)^{-1/3} \left(\frac{\mu_{\mathrm{w}}}{\mu_{\mathrm{m}}}\right)^{-0.14}$$
$$= c_4 \left(\frac{L}{D_{\mathrm{e}} Re Pr}\right)^{-1/3} \left(\frac{\mu_{\mathrm{w}}}{\mu_{\mathrm{m}}}\right)^{-0.14} \tag{59}$$

where c_4 will depend both on the thermal boundary condition and the plate geometry, and is found to have values from 1.2 to 4.5. The dependence of the plate length L in the foregoing equation is not correct and should be replaced by a function of the corrugation pitch. JACKSON and TROUPE [55] proposed a exponent of 0.38 on the Reynolds number in Equation (59), and this has been confirmed in simulation studies.

Friction Factor Correlations. Based on the analogy to packed beds, the Fanning factor is presented in the form

$$f = c_5 + c_6 / Re \tag{60}$$

where the first and second terms on the right-hand side represent the contributions of turbulent and laminar effects respectively. This type

of equation could therefore be expected to correlate data in both the laminar and turbulent regimes.

For most plate designs, flow is turbulent and the following equation correlates pressure drop data better:

$$f = c_7 Re^{c_8} \tag{61}$$

where c_7 and c_8 are empirical constants. As an illustration of Equations (60) and (61), the correlations for the chevron plate (Fig. 6c) with $\beta = 30°$ are [56]:

$$f = \begin{cases} 0.093 + 57.5/Re & \text{for } 260 < Re < 3000 \\ 0.898 Re^{-0.26} & \text{for } 3000 < Re < 50000 \end{cases} \tag{62}$$

A very limited amount of other published correlations (design data) for plate exchangers are summarized in [3].

6.3.3. Extended Surface Exchangers

Compact exchanger surface basic data are usually presented in terms of j and f vs. Re. In these groups, the hydraulic diameter D_h is used, directly or indirectly, arbitrarily but consistently as a characteristic dimension. Although j and f data are applicable to any geometrically similar surface, as soon as the basic geometry is changed (such as an offset strip-fin geometry changed from 400 to 600 fins/m), the original j and f data are no longer applicable. This is because D_h is not a universal characteristic dimension. A great variety of compact surface geometries are available, and generally these different geometries will have different j and f data. Such surface basic data have been provided in [39] for over 60 plate-fin surface geometries: plain fins, wavy fins, offset strip fins, louver fins, perforated fins, and pin fins. Correlations for offset strip fin geometry are now presented as an illustration. Some additional surface basic data are provided in [27].

Offset Strip Fins. This is one of the most widely used enhanced fin geometries in compact heat exchangers. In addition to the fin spacing and fin height, the major variables are the fin thickness and fin strip length in the flow direction. The situation is complicated by burrs formed on leading and trailing fin edges during the manufacturing operation.

The following multiple regression power-law correlations of Joshi and Webb [58] are recommended for design use. They are based on the test data for 21 test cores with a wide variation in geometrical dimensions of the offset strip fin. Flow visualization measurements of Joshi and Webb show that the Reynolds number ($G D_h/\mu$) at which the wake departs from laminar flow is given by

$$Re^* = 257.2 \left(\frac{l_{ef}}{s'}\right)^{1.23} \left(\frac{\delta_f}{l_{ef}}\right)^{0.58} \cdot \left[\frac{\delta_f}{D_h} + 1.328 \left(\frac{l_{ef}}{D_h}\right)^{0.5} Re^{-0.5}\right]^{-1} \tag{63}$$

The j and f correlations for $Re < Re^*$ are given by

$$f_L = 8.12 Re^{-0.74} \left(\frac{l_{ef}}{D_h}\right)^{-0.41} \left(\frac{s}{b}\right)^{-0.02} \tag{64}$$

$$j_L = 0.53 Re^{-0.56} \left(\frac{l_{ef}}{D_h}\right)^{-0.15} \left(\frac{s}{b}\right)^{-0.14} \tag{65}$$

The correct exponent on Re is -0.56; the exponent in [58] is not correct.

The correlations for $Re > Re^* + 1000$ are given by

$$f_T = 1.12 Re^{-0.36} \left(\frac{l_{ef}}{D_h}\right)^{-0.65} \left(\frac{\delta_f}{D_h}\right)^{0.17} \tag{66}$$

$$j_T = 0.21 Re^{-0.40} \left(\frac{l_{ef}}{D_h}\right)^{-0.24} \left(\frac{\delta_f}{D_h}\right)^{0.02} \tag{67}$$

The j factor in the transition region between $Re^* < Re < Re^* + 1000$ is a log-linear interpolation between j_L (at Re^*) and j_T (at $Re^* + 1000$). A similar method is used for the friction factor. In the above equations, s is the fin pitch, l_{ef} the strip length, b the plate spacing, and δ_f the fin thickness.

The correlation predicted 82 % of the f data and 91 % of the j data within ± 15 %. The geometric parameters of the test arrays on which Equations (64) – (67) are based are $0.13 < s/b < 1.0$, $0.012 < \delta_f/l_{ef} < 0.048$, and $0.04 < \delta_f/s < 0.20$.

Published correlations on many plate – fin type surface geometries are presented in [57], [59].

7. Two-Phase Heat-Transfer and Pressure-Drop Correlations

Since two-phase flows are much more complex, it is essential to have the basic understanding of the following topics before conducting a heat exchanger design: flow patterns, two-phase pressure-drop correlations, condensation correlations, and pool boiling and forced convection boiling correlations, which are discussed in this chapter.

7.1. Flow Patterns

Flow regimes for a single-phase fluid flow are "laminar", "transition", and "turbulent". In a sharp-cornered pipe, all three regimes may exist simultaneously. In addition, secondary flows may exist such as in a curved pipe or in a straight pipe with a twisted tape. Flow separation and reattachment may also take place such as in flow over an interrupted heat-exchanger surface or over a tube bank. Knowledge of these characteristics is important for heat-transfer and pressure-drop correlations and analyses for single-phase exchangers.

These characteristics are also important for two-phase correlations. However, the geometry

or topology of two phases is even more important for pressure-drop and heat-transfer correlations and analyses. The liquid and gas or vapor flowing in or over a tube exhibit a variety of configurations known as *flow patterns.* A particular flow pattern is dependent upon the pipe geometry, relative magnitudes of gas and liquid flows, fluid properties, and operating conditions (flow rates, pressure, temperature, boundary conditions, heat flux, etc.). Many flow patterns have been identified [60–62]. Typical flow patterns in vertical (upflow) and horizontal pipes are shown in Figure 38 [62], and those for vertical (upflow) and horizontal shellside are shown in Figure 39 [63].

For flow regime-based correlations (which are more accurate) and understanding of the operating characteristics of a system, knowledge of transitions between flow patterns is very important. These transitions are presented in the form of a two-dimensional flow pattern map. Two axes of this map represent dimensional or dimensionless groups of flow parameters and fluid properties. Over 30 such maps have been presented in literature. The transition boundaries are represented either by lines or short regions. Usually, the transition is not abrupt; to indicate the uncertainty associated with the flow pattern changes, the region is more representative of the transition boundaries. TAITEL et al. developed semi-empirical models for transition between the flow patterns [64], [65]. WEISMAN et al. [66], [67] developed the flow pattern maps empirically, and these are in reasonably good agreement with other popular flow pattern maps. Their flow pattern maps are presented in Figures 40 and 41 with the functions φ_1 and φ_2 in Table 14. GRANT and MURRAY empirically developed the flow pattern maps for the shellside or flow normal to a tube bank (both vertical and horizontal flow) as shown in Figure 42 [68]. The flow pattern transition boundaries, shown by solid lines in this figure, indicate a mean of the transition regions. Note that v_{gs} in Figures 40, 41, and 42 and Table 14 represents the superficial gas velocity (the rate of volumetric flow of the gas phase in the two-phase mixture divided by the total flow area); similarly v_{ls} represents the superficial liquid velocity.

7.2. Two-Phase Pressure-Drop Correlations

Two-phase pressure drop in tubes consists of mainly three components: friction, momentum change (acceleration/deceleration), and gravity.

$$\Delta p = \Delta p_{\mathrm{f}} + \Delta p_{\mathrm{m}} + \Delta p_{\mathrm{hs}} \tag{68}$$

The entrance and exit pressure losses, usually considered in compact heat exchanger application, are neglected because (1) no two-phase data exist for these pressure losses, and (2) they represent a small fraction of the total pressure drop and are well within the uncertainty involved in the two-phase Δp prediction.

7.2.1. Intube Pressure Drop

Expressions and correlations for pressure-drop components of Equation (68) for two-phase flow in a circular tube are now summarized.

The pressure drop or rise caused by an elevation change (hydrostatic effect) is given by

$$\Delta p_{\mathrm{hs}} = \pm \frac{g}{g_{\mathrm{c}}} \sin\theta \int_0^L [\alpha \varrho_{\mathrm{g}} + (1-\alpha)\, \varrho_{\mathrm{l}}]\, dz \tag{69}$$

where the angle of inclination θ is measured from the horizontal, the "−" sign stands for a downflow (pressure rise) and the "+" sign for an upflow (pressure drop); α is the void fraction.

A void fraction correlation based on steam–water data obtained by THOM has been fitted to a curve by BUTTERWORTH as [69]

$$\alpha = \left[1 + \left(\frac{1-x}{x}\right)\left(\frac{\varrho_{\mathrm{g}}}{\varrho_{\mathrm{l}}}\right)^{0.89}\right]\left(\frac{\mu_{\mathrm{l}}}{\mu_{\mathrm{g}}}\right)^{0.18} \tag{70}$$

For the homogeneous model, α is given by

$$\alpha = \left[1 + \left(\frac{1-x}{x}\right)\left(\frac{\varrho_{\mathrm{g}}}{\varrho_{\mathrm{l}}}\right)\right]^{-1} \tag{71}$$

When Δp_{hs} is a dominant term in Equation (68) (i.e., 1/2 to 2/3 of the total Δp), such as for low velocity and low pressure applications, Equation (69) should be used for calculating Δp_{hs}. For other cases, a homogeneous model is fairly accurate; Equation (69) then reduces to

$$\Delta p_{\mathrm{g}} = \pm \frac{g}{g_{\mathrm{c}}} \sin\theta \int_0^L \varrho_{\mathrm{hom}}\, dz \tag{72}$$

where

$$\frac{1}{\varrho_{\mathrm{hom}}}=\frac{x}{\varrho_{\mathrm{g}}}+\frac{1-x}{\varrho_{\mathrm{l}}} \tag{73}$$

The momentum pressure drop or rise from cross section 1 to 2 is given by

$$\Delta p_{\mathrm{m}}=\frac{G^2}{g_{\mathrm{c}}}\left[\left(\frac{x^2}{\alpha\varrho_{\mathrm{g}}}+\frac{(1-x)^2}{(1-\alpha)\varrho_{\mathrm{l}}}\right)_2-\left(\frac{x^2}{\alpha\varrho_{\mathrm{g}}}+\frac{(1-x)^2}{(1-\alpha)\varrho_{\mathrm{l}}}\right)_1\right] \tag{74}$$

which for a homogeneous model reduces to

$$\Delta p_{\mathrm{m}}=\frac{G^2}{g_{\mathrm{c}}}\left(\frac{1}{\varrho_{\mathrm{hom},2}}-\frac{1}{\varrho_{\mathrm{hom},1}}\right) \tag{75}$$

The pressure drop due to friction is given by

$$\Delta p_f=\Delta p_{f,\mathrm{lo}}\varphi_{\mathrm{lo}}^2=f_{\mathrm{lo}}\frac{4L}{D_{\mathrm{h}}}\frac{G^2}{2g_{\mathrm{c}}\varrho_{\mathrm{l}}}\varphi_{\mathrm{lo}}^2 \tag{76}$$

where $\Delta p_{f,\mathrm{lo}}$ is the frictional pressure drop for liquid flowing alone, in the same tube, with a mass flow rate equal to the total mass flow rate of the two-phase flow. φ_{lo}^2 is the two-phase friction multiplier. Extensive comparisons and assessments of 25 000 data points (with and without heat transfer) have been made in [70–72] to arrive at specific models for φ_{lo}^2 (18 different available models for φ_{lo}^2 have been reported in the literature). f_{lo} is the single-phase friction factor for liquid (with total flow rate) flowing in the tube. f_{lo} is given by

$$f_{\mathrm{lo}}=0.079Re_{\mathrm{lo}}^{-0.25} \tag{77}$$

where $Re_{\mathrm{lo}}=GD_{\mathrm{h}}/\mu_{\mathrm{l}}$.

For high reduced pressures (p/p_{cr}), the homogeneous model yields accurate results, and is given by

$$\varphi_{\mathrm{lo}}^2=1+x\left(\frac{\varrho_{\mathrm{l}}}{\varrho_{\mathrm{g}}}-1\right) \tag{78}$$

Hewitt [73] recommends three different correlations for different ranges of viscosities and mass velocities as summarized next. Friedel [72] and Chisholm [74] developed correlations for many fluids for a wide range of variables. Friedel's correlation, more accurate for $\mu_{\mathrm{l}}/\mu_{\mathrm{g}}<1000$, is given by

$$\varphi_{\mathrm{lo}}^2=S_1+3.24S_2S_3Fr^{-0.045}We^{-0.035} \tag{79}$$

where

$$S_1=(1-x)^2+x^2\varrho_{\mathrm{l}}f_{\mathrm{go}}/\varrho_{\mathrm{g}}f_{\mathrm{lo}} \tag{80}$$

$$S_2=x^{0.78}(1-x)^{0.224} \tag{81}$$

$$S_3=\left(\frac{\varrho_{\mathrm{l}}}{\varrho_{\mathrm{g}}}\right)^{0.91}\left(\frac{\mu_{\mathrm{g}}}{\mu_{\mathrm{l}}}\right)^{0.19}\left(1-\frac{\mu_{\mathrm{g}}}{\mu_{\mathrm{l}}}\right)^{0.7} \tag{82}$$

$$Fr=\frac{G^2}{gd_{\mathrm{i}}\varrho_{\mathrm{hom}}^2} \tag{83}$$

$$We=\frac{G^2d_{\mathrm{i}}}{g_{\mathrm{c}}\sigma\varrho_{\mathrm{hom}}} \tag{84}$$

and ϱ_{hom} is given by Equation (73).

Chisholm's correlation, more accurate for $\mu_{\mathrm{l}}/\mu_{\mathrm{g}}>1000$ and $G>100\,\mathrm{kg/m^2\,s}$, is given by

$$\varphi_{\mathrm{lo}}^2=1+\left(\boldsymbol{\Gamma}^2-1\right)\cdot\left[Bx^{(2-n)/2}(1-x)^{(2-n)/2}+x^{2-n}\right] \tag{85}$$

where

$$\boldsymbol{\Gamma}^2=\frac{\Delta p_{\mathrm{f,go}}}{\Delta p_{\mathrm{f,lo}}} \tag{86}$$

$n=$ exponent in Blasius type equation
$B=$ coefficient as given in Table 15.

Table 15. Values of B in Equation (85) for smooth tubes [74]

Γ	G, kg/m^2 s	B
≤ 9.5	<500	4.8
	$500<G<1900$	$2400/G$
	≥ 1900	$55/G^{0.5}$
$9.5<\Gamma<28$	≤ 600	$520/(\Gamma G^{0.5})$
	≥ 600	$21/\Gamma$
≥ 28		$15\,000/(\Gamma^2 G^{0.5})$

Finally, the Lockhart–Martinelli correlation [75], more accurate for $\mu_{\mathrm{l}}/\mu_{\mathrm{g}}>1000$ and $G<100\,\mathrm{kg/m^2\,s}$, is given in terms of $\Delta p_{\mathrm{f,l}}$ or $\Delta p_{\mathrm{f,g}}$ by

$$\Delta p_{\mathrm{f}}=\Delta p_{\mathrm{f,l}}\varphi_{\mathrm{l}}^2=\Delta p_{\mathrm{f,g}}\varphi_{\mathrm{g}}^2 \tag{87}$$

where $\Delta p_{\mathrm{f,l}}$ is the frictional pressure drop for liquid flowing alone with actual liquid flow (and not total flow) rate in the total cross-sectional

area of the tube; φ_l^2 is the corresponding two-phase friction multiplier. $\Delta p_{f,g}$ and φ_g^2 are defined similarly for gas flowing alone. The correlations for φ_l^2 and φ_g^2 are given by [60]:

$$\varphi_l^2 = 1 + \frac{c}{X} + \frac{1}{X^2} \tag{88}$$

$$\varphi_g^2 = 1 + cX + X^2 \tag{89}$$

where

$$X^2 = \frac{\Delta p_{f,l}}{\Delta P_{f,g}} \tag{90}$$

and the value of c is dependent on the four possible single-phase regimes for liquid and gas streams in the tube.

$$c = \begin{cases} & \text{liquid} \quad \text{gas} \\ 20 & \text{turbulent} - \text{turbulent} \quad (\text{tt}) \\ 10 & \text{turbulent} - \text{viscous} \quad (\text{tv}) \\ 12 & \text{viscous} - \text{turbulent} \quad (\text{vt}) \\ 5 & \text{viscous} - \text{viscous} \quad (\text{vv}) \end{cases} \tag{91}$$

The foregoing correlations for predicting the adiabatic two-phase pressure drop are one of the best accurate correlations which have been reported in literature. Usually, the predicted two-phase pressure drop will have an uncertainty of ca. $\pm 20\,\%$ under ordinary operating conditions and with ordinary fluids; the error can be as high as $\pm 50\,\%$ or more for unusual operating conditions and fluids.

During the condensation process, since mass transfer takes place at the liquid – vapor interface, a correction needs to be made to the foregoing value of Δp_f in Equation (76). This correction is done on a local basis [76].

$$\frac{\Delta p_f}{\Delta z} = \frac{4}{d_i} \tau_i c_f \tag{92}$$

where

$$c_f = \frac{\gamma}{1 - \exp(-\gamma)} \text{ and } \gamma = \frac{W \Delta x}{\Delta A} \frac{v_g - v_i}{\tau_i} \tag{93}$$

Here τ_i is the interfacial shear stress, c_f is the correction factor for the frictional pressure gradient for the effect of mass transfer to the vapor – liquid interface, and Δx is the change in quality over surface area ΔA. τ_i is determined using the Martinelli parameter [76].

Equations (92) and (93) are solved iteratively to determine Δp_f for each increment Δz with an initial assumption that c_f is 1, and the sum of these Δp_f increments could result in the total Δp_f for the tube. At high condensing rates, the foregoing cumulative correction c_f to Δp_f can be as much as a factor of 2.

The frictional pressure drop for condensation or boiling must be calculated in a stepwise manner for small increments of Δz for which changes in quality, fluid properties, and other conditions are only moderate.

7.2.2. Shellside (Tube Bundle) Pressure Drop

A review on two-phase pressure drop for horizontal and vertical crossflow on the shellside is presented in [77]. Crossflow in a baffled horizontal heat exchanger with horizontal or vertical baffle cuts is referred to as "horizontal crossflow". Such flow was investigated by Grant and Chisholm [78] using an air – water system. Their correlation is given by Equation (85), with the values of the parameter B given in Table 16 [63], [78] for the crossflow zone. For the window zone, $n = 0$ for Equation (85) with $B = 0.25$ for vertical up-and-down flow, and $B = 2/(\Gamma + 1)$ for horizontal side-to-side flow.

For vertical crossflow (upflow) in a horizontal tube bundle, Schrage's correlation is recommended for φ_l^2 in Equation (87) as follows [79]:

$$\varphi_l^2 = 1 + \frac{c}{X_{tt}} + \frac{c_5}{X_{tt}^2} \tag{94a}$$

where

$$c = c_1 Fr_l^{c_2} \ln X_{tt} + c_3 Fr_l^{c_4} \tag{94b}$$

Here constants $c_1 - c_5$ are given in Table 17. For slug and spray flows, Equations (94 a and b), i.e., the constants $c_1 - c_5$ are valid for $Fr_l > 0.15$. For $Fr_l \leq 0.15$, the following correlation can be used [80]:

$$\varphi_l^2 = 1 + \frac{8}{X_{tt}} + \frac{1}{X_{tt}^2} \tag{95a}$$

where

$$X_{tt} = \left(\frac{1-x}{x}\right)^{0.9} \left(\frac{\varrho_g}{\varrho_l}\right)^{0.5} \left(\frac{\mu_l}{\mu_g}\right)^{0.1} \tag{95b}$$

Equation (95 a) is valid for $X_{tt} < 0.2$.

Table 16. Values of B and n of Equation (85) for the two-phase pressure drop for flow normal to a tube bank [63], [67]

Flow type	B	n
Vertical up-and-down spray and bubble	1	0.37
Horizontal side-to-side spray and bubble	0.75	0.46
Horizontal side-to-side stratified and stratified spray	0.25	0.46

Table 17. Coefficients for the two-phase friction multiplier correlation of Equation (94)

Flow pattern [a]	c_1	c_2	c_3	c_4	c_5
Bubbly	0.036	1.51	7.79	−0.057	0.774
Slug [b]	2.18	−0.643	11.6	0.233	1.09
Spray [b]	0.253	−1.50	12.4	0.207	0.205

[a] Flow pattern evaluated with Grant and Chisholm [68] flow pattern map
[b] If $Fr_1 \leq 0.15$, use Ishihara et al. [78] correlation

7.2.3. Other Geometries

Information on the two-phase pressure drop in compact heat exchanger surfaces is given in [11].

7.3. Heat-Transfer Correlations for Condensation

The process of converting vapor into liquid by removing heat from a system is defined as condensation. This occurs when the vapor is cooled below its saturation temperature causing nucleation of droplets. Such nucleation may occur homogeneously within the vapor (fog formation) or heterogeneously on the walls of the equipment. The latter may be categorized as dropwise or filmwise condensation. A number of different condensation types exist:

1) *Film Condensation.* The condensate forms a continuous liquid film on the cooled surface. This is the most common type of condensation in industrial equipment.
2) *Dropwise Condensation.* Here the condensate forms droplets on the cooled surface. High heat-transfer coefficients are obtained with dropwise condensation but it is difficult to maintain in industrial exchangers. Dropwise condensation occurs only with liquids having a high surface tension, such as water on specially treated surfaces.
3) *Condensation of Vapor Mixtures Forming Immiscible Liquids.* Here the condensate consists of a film of one component in which drops of the second component float and/or adhere to the cooled surface.
4) *Direct Contact Condensation.* This occurs when the vapor is brought directly into contact with a cold liquid.
5) *Homogeneous Condensation.* Here the vapor condenses in very small droplets forming fog. This occurs when a vapor and a noncondensable gas are cooled below the saturation temperature. While fogging does occur occasionally in industrial exchangers, it is not the desired method to condense the vapor.

In film condensation, the condensate wets the surface and forms a continuous liquid film. The behavior of this liquid film is governed by the normal fluid dynamic laws with gravity, vapor shear, and surface tension forces, either singly or together, acting to promote the removal of the condensate film. Two major condensation mechanisms are the gravity-controlled (vapor space) condensation and vapor shear-controlled (forced convective) condensation. Resistance to heat transfer during condensation is shown in Figure 43. For a pure saturated vapor, the resistance at the vapor – liquid interface is small, and may be neglected for a first approximation. It can, however, be significant for noncondensable gases or a multicomponent vapor mixture.

Figure 43. Heat-transfer resistances during condensation a) Temperature profile for pure saturated vapor; b) Temperature profile for superheated vapor or noncondensable gas

Heat must also be transferred through the condensate liquid film to the wall and then to

the coolant. In the case of a pure saturated vapor, this temperature drop across the liquid film represents the prime resistance to heat transfer. Techniques that reduce the condensate film thickness or promote a higher "effective" conductivity will therefore increase the heat-transfer coefficient on the condensing side. In the case of a vapor containing noncondensables or with a multicomponent vapor mixture, the gas phase resistance often dominates the overall condensing side coefficient; increase in the condensate film coefficient may not promote a comparable increase in overall condensation rate.

Condensation coefficients can vary significantly depending on the condensation rates, flow patterns, tube geometry, etc. During the condensation process, flow varies from being mostly vapor at the inlet to mostly liquid at the outlet in many processes, or from shear-dominated to gravity-dominated flows, and goes through a number of flow regimes. During this process, the condensing heat-transfer coefficient and temperature difference are evaluated as functions of the local quality and other parameters or variables of importance. Subsequent stepwise numerical or graphical integration would then yield the required surface area or the heat duty whichever is unknown. In only a few simple condensers would a single calculation suffice for a design.

At high-vapor shear, the condensate layer is turbulent and the heat-transfer coefficients are independent of the tube orientation. At low shear rates, gravity controls the effect of tube orientation. At intermediate shear rates where wavy, slug, or bubble-type flow patterns occur, the local heat-transfer coefficient can fluctuate widely. Currently, this intermediate region is calculated by prorating the high and low shear coefficients based on a parameter used to define these limits on two-phase flow maps. The most accurate condensation correlations available in the open literature are now summarized. A detailed study on the subject is given in [81–84].

7.3.1. Condensation Inside a Horizontal Tube

The two most common flow patterns during condensation within a horizontal tube are annular (vapor shear-dominated) flow and stratified (gravity-dominated) flow. Breber et al. [85] have provided the following criteria to identify these flow patterns:

$$\text{Annular flow}: j_g^* > 1.5 \tag{96a}$$

$$\text{Stratified flow}: j_g^* < 0.5 \tag{96b}$$

For intermediate values of j_g^*, a linear interpolation of the heat-transfer coefficient calculated for annular and stratified flows must be used. Here the Wallis parameter j_g^* is the dimensionless gas-phase mass velocity defined as

$$j_g^* = \frac{xG}{[g d_i \varrho_g (\varrho_l - \varrho_g)]^{1/2}} \tag{97}$$

Equation (96) is valid when the Martinelli parameter X_{tt} in Equation (95 b) is less than one.

For annular flows, the Nusselt-type laminar flow models predict heat-transfer coefficients that are too low; hence, turbulent flow models must be used to enable better prediction. The following empirical correlation based on 473 experimental data points for steam, refrigerants, and other organics, predicts condensation coefficients with a mean deviation of 15 % [86]:

$$Nu_z = Nu_l \left[(1-x)^{0.8} + \frac{3.8 x^{0.76} (1-x)^{0.04}}{p_r^{0.38}} \right] \tag{98}$$

where $p_r = p/p_{cr}$ is the reduced pressure, and Nu_l is the Nusselt number assuming that the total flow rate is the liquid flow rate in the tube, and is calculated from

$$Nu_l = 0.023 Re_{lo}^{0.8} Pr_l^{0.4} \tag{99}$$

Alternatively, there are a number of analytical correlations available for annular flow condensation inside a tube based on heat-transfer – momentum-transfer analogy, which are summarized in [81–84].

For stratified flows, the condensate forms a thin film on the top portion of the tube walls, then drains toward the bottom of the tube and forms a thick film. The stratified layer at the bottom flows axially due to the action of shear forces. The Nusselt equation is used for the upper condensate film portion, and the heat transfer from the condensate layer flowing along the bottom of the tube is neglected, correcting for the tube area covered by the stratified layer. In order to determine the peripheral mean heat-transfer coefficient based on the entire perimeter, the

following modified Nusselt equation applies for stratified flow [81], [83]:

$$Nu_z = \frac{h_z d_\mathrm{i}}{k_\mathrm{l}} = \Omega \left[\frac{\varrho_\mathrm{l} (\varrho_\mathrm{l} - \varrho_\mathrm{g}) g i'_\mathrm{lg} d_\mathrm{i}^3}{k_\mathrm{l} \mu_\mathrm{l} (T_\mathrm{sat} - T_\mathrm{w})} \right]^{1/4} \tag{100}$$

where the correction factor Ω is based on the void fraction:

$$\Omega = 0.728 \left\{ 1 + \left(\frac{1-x}{x} \right) \left(\frac{\varrho_\mathrm{g}}{\varrho_\mathrm{l}} \right)^{2/3} \right\}^{-3/4} \tag{101}$$

and

$$i'_\mathrm{lg} = i_\mathrm{lg} + \frac{3}{8} c_\mathrm{p,l} (T_\mathrm{sat} - T_\mathrm{w}) \tag{102}$$

7.3.2. Condensation Inside a Vertical Tube

The condensation-coefficient correlations for vertical tubes depend on whether the vapor flow is downward or upward.

For downward vapor shear-controlled flow (see criteria of Eq. (96 a)), an annular flow pattern exists, and the correlation of Equation (98) can be used. For downward gravity-controlled flow, the following correlations for the local heat-transfer coefficient are recommended which are dependant on the film (laminar, wavy, or turbulent) Reynolds number $Re_{\Gamma,z}$ [81], [82]:

$$\frac{h_z}{k_\mathrm{l}} \left[\frac{\mu_\mathrm{l}^2}{\varrho_\mathrm{l} (\varrho_\mathrm{l} - \varrho_\mathrm{g}) g} \right]^{1/3} = \begin{cases} 1.1 Re_{\Gamma,z}^{-1/3} & \text{for } Re_{\Gamma,z} \leq 33 \\ 0.76 Re_{\Gamma,z}^{-0.22} & \text{for } 33 < Re_{\Gamma,z} < 1600 \\ 0.023 Re_{\Gamma,z}^{1/4} Pr_\mathrm{l}^n & \text{for } Re_{\Gamma,z} \geq 1600 \end{cases} \tag{103}$$

where

$$Re_{\Gamma,z} = 4\Gamma_\mathrm{z}/\mu_\mathrm{l} \tag{104}$$

$$\Gamma_\mathrm{z} = \frac{\varrho_\mathrm{l} (\varrho_\mathrm{l} - \varrho_\mathrm{g}) g \delta^3}{3\mu_\mathrm{l}};$$

$$\delta = \left[\frac{4\mu_\mathrm{l} k_\mathrm{l} z (T_\mathrm{sat} - T_\mathrm{w})}{\varrho_\mathrm{l} (\varrho_\mathrm{l} - \varrho_\mathrm{g}) g i'_\mathrm{lg}} \right]^{1/4} \tag{105}$$

Although the Pr_l exponent $n = 0.5$ is recommended [81], [82], it appears to be high for the turbulent film, and a value of 0.33 may be a better choice [81]. Expressions for the mean heat-transfer coefficients (counterpart of Eq. (103)) are given in [82].

For upward vapor flows, the interfacial shear will retard the condensate drainage, the film will thicken, and if the vapor velocity is high, it will cause flooding (preventing downflow of condensate). Based on the air – water system, WALLIS [87] has provided the following criterion for the onset of flooding:

$$(v_\mathrm{g}^*)^{1/2} + (v_\mathrm{l}^*)^{1/2} = c \tag{106}$$

where

$$v_\mathrm{g}^* = \frac{v \varrho_\mathrm{g}^{1/2} \mathrm{g}}{[g d_\mathrm{i} (\varrho_\mathrm{l} - \varrho_\mathrm{g})]^{1/2}} \tag{107}$$

$$v_\mathrm{l}^* = \frac{v_\mathrm{l} \varrho_\mathrm{l}^{1/2}}{[g d_\mathrm{i} (\varrho_\mathrm{l} - \varrho_\mathrm{g})]^{1/2}} \tag{108}$$

The gas and liquid phase velocities v_g and v_l should be calculated at the bottom of the tube where they are at a maximum. While WALLIS assumes the value of c as 0.725, BUTTERWORTH suggests a conservative value of 0.6 and a more appropriate value as follows [88]:

$$c^2 = 0.53 F_1 F_2 \tag{109}$$

$$F_1 = (\sigma_\mathrm{l}/\sigma_\mathrm{w})^{0.5} \tag{110}$$

where σ_w is the surface tension of water at room temperature. F_2 is unity if the tube is cut at a right angle to the tube axis; otherwise, it is greater than unity.

The condensing heat-transfer coefficient for upward vapor flow is reduced by a factor of 0.7 to 1.0 compared to that calculated from the Nusselt theory depending upon the vapor velocity. It is given by

$$\frac{h_\mathrm{m}}{k_\mathrm{l}} \left[\frac{\mu_\mathrm{l}^2}{\varrho_\mathrm{l} (\varrho_\mathrm{l} - \varrho_\mathrm{g}) g} \right]^{1/3} = 1.47 Re_{\Gamma,\mathrm{L}}^{-1/3} c \tag{111}$$

where

$$Re_{\Gamma,\mathrm{L}} = 4\Gamma_\mathrm{L}/\mu_\mathrm{l};\ \Gamma_\mathrm{L} = q''_\mathrm{ave} L / i'_\mathrm{lg} \tag{112}$$

where the value of c ranges from 0.7 to 1.0 [81], and $L = \pi d_\mathrm{i}$.

7.3.3. Condensation Outside Horizontal Tube Bundles

The mean transfer coefficient for gravity-controlled laminar film condensation over a single horizontal tube is given by Nusselt as

$$Nu_{\mathrm{m}}=\frac{h_{\mathrm{m}}d_0}{k_{\mathrm{l}}}=0.725\left[\frac{d_{\mathrm{o}}^3\varrho_{\mathrm{l}}\left(\varrho_{\mathrm{l}}-\varrho_{\mathrm{g}}\right)g\,i'_{\mathrm{lg}}}{k_{\mathrm{l}}\mu_{\mathrm{l}}\left(T_{\mathrm{sat}}-T_{\mathrm{w}}\right)}\right]^{1/4} \tag{113}$$

For crossflow over a tube bundle, dripping of condensate from row to row and the vapor velocity influence the heat-transfer coefficient for subsequent rows. Empirically, the mean heat-transfer coefficient for N rows is given by

$$h_{\mathrm{m}}=h_{\mathrm{m},1}N_{\mathrm{r}}^{-1/6} \tag{114}$$

where $h_{\mathrm{m},1}$ for the first tube row is given by Equation (113).

For a circular tube bundle (such as in X shells), the effective number of tubes in a vertical path is given empirically by

$$N_{\mathrm{r}}=0.78d_{\mathrm{B}}/X_{\mathrm{l}} \tag{115}$$

where d_{B} is the bundle diameter and X_{l} is the longitudinal vertical tube pitch.

At moderate vapor shear, the following equations are recommended:

$$Nu=c\left(\chi^4Re^2+Nu_{\mathrm{m}}^4\right)^{1/4} \tag{116}$$

where

$$c=\begin{cases}1.0 & \text{for staggered tubes}\\ 0.8 & \text{for inline tubes}\end{cases} \tag{117}$$

$$\chi=0.9\left[1+\frac{1}{S_4S_5}\right]^{1/3} \tag{118}$$

$$S_4=\left[\frac{\varrho_{\mathrm{l}}\mu_{\mathrm{l}}}{\varrho_{\mathrm{g}}\mu_{\mathrm{g}}}\right]^{1/2} \tag{119}$$

$$S_5=\frac{c_{\mathrm{p,l}}\left(T_{\mathrm{sat}}-T_{\mathrm{w}}\right)}{Pr_{\mathrm{l}}i_{\mathrm{lg}}} \tag{120}$$

$$Re=\frac{W\,d_0\,\varrho_{\mathrm{l}}}{A_{\mathrm{f_1}}\,\mu_{\mathrm{l}}\varrho_{\mathrm{g}}} \tag{121}$$

Nu_{m} in Equation (116) is defined in Equation (113). The first term in the parenthesis in Equation (116) represents the velocity effect and the second term is the conventional Nusselt condensation equation. Equation (116) is used for either horizontal or vertical downflow.

TABOREK [89] suggested a simpler and perhaps equally good method. For an ideal bundle,

$$Nu=0.3Re^{0.6}Pr^{0.4}\left(1+\varrho_{\mathrm{l}}/\varrho_{\mathrm{g}}\right)^{1/2} \tag{122}$$

In a baffled exchanger, the effect of leakage streams on the ideal flow through the bundle must be allowed for.

At very high vapor shear the coefficients appear to decrease. This has been attributed to (1) hydrodynamic trapping of condensate between tubes, which then reduces the condensing area, or (2) local pressure reductions and, hence, lower temperature difference. No criteria are available to enable prediction of this phenomenon.

7.3.4. Condensation over Finned Tubes

Finned tubes are widely used in refrigeration and air-conditioning systems. The short fins, ca. 1.6 mm high and with 630 – 1050 fins/m, are extruded from the tube walls, resulting in an approximately three- to fourfold increase in external area. BEATTY and KATZ [90] correlated data by assuming that the fins act as vertical surfaces and the tube between the fins as a horizontal tube. They derived an equivalent diameter expression which, when substituted in a theoretical equation, (or empirical correlation, Eq. (98)) predicted the coefficients for a single tube in quiescent vapor. This equivalent diameter D_{e} is

$$D_{\mathrm{e}}=\left[\frac{1.3A_{\mathrm{f}}\eta_{\mathrm{f}}}{A_{\mathrm{ef}}\,l^{1/4}}+\frac{A_{\mathrm{bt}}}{A_{\mathrm{ef}}\,d_{\mathrm{o}}^{1/4}}\right]^{-1/4} \tag{123}$$

where

$A_{\mathrm{f}}=$ actual fin area
$A_{\mathrm{bt}}=$ horizontal bare tube (base) area
$\eta_{\mathrm{f}}=$ fin efficiency
$A_{\mathrm{ef}}=A_{\mathrm{f}}\,\eta_{\mathrm{f}}+A_{\mathrm{bt}}$
$l=A_{\mathrm{f}}/2\,d_{\mathrm{e}}$

The fin efficiency η_{f} is essentially 1.0 for copper tubes but it needs to be taken into account when stainless steel tubes are used (since $\eta_{\mathrm{f}}<1.0$). The heat transfer of low finned tubes is affected by the surface tension of condensate. Liquids with high surface tension, such as water, flood the spaces between the fins and result in a substantial reduction of heat transfer.

The lower portion of the tubes tend to be flooded with a condensate holdup, and poor heat transfer would be expected. However, it appears that for the upper portion, the effect of surface tension is to thin the condensate layer on the fins and to improve the heat transfer; the net result seems to be a cancellation of these effects and Equation (123) still holds.

In process exchangers, there will be an effect of tube rows and vapor shear. Much of the information for these condensers is proprietary but it seems that using Equation (123) for a single tube coefficient and then applying the row and shear corrections given above for the plain tubes should produce reasonable coefficients.

Condensation inside or outside of other enhanced tubes and surfaces is covered in [11], [83].

7.3.5. Condensation Outside Vertical Tube Bundles

For parallel flow outside vertical tubes, the condensation heat-transfer coefficient is computed using the correlations presented earlier for condensation inside a circular tube with alteration: the circular tube diameter is replaced by the hydraulic diameter of the tube bundle for parallel flow outside the tube bundle.

7.3.6. Condensation of Mixtures

While very high heat-transfer coefficient can be achieved during the condensation of a pure vapor, the presence of a small amount of noncondensable gas or a more volatile vapor can introduce a significant thermal resistance to the heat flow at the interface, and reduce the heat-transfer rate significantly. A schematic of the condensation of a vapor in the presence of a noncondensable gas is shown in Figure 43.

Four main approaches have been used in the development of design procedures for various mixtures of condensable vapors and noncondensable gases. These are approximate techniques, film models, penetration models, and boundary layer models. Specific methods and design procedures for condensers with mixtures are summarized in Section 9.1.3 and further details are given in [91].

7.4. Heat-Transfer Correlations for Boiling and Evaporation

Forced convective vaporization (boiling and evaporation) in confined channels (circular tubes, annuli, ducts of other cross sections, and flow over tube bundles) is a very important industrial problem. The fluid can be a liquid and its vapor, or a mixture of fluids in liquid and/or vapor phases. Because of the heat addition along the flow length, the liquid will go through a series of flow regimes, such as shown in Figure 44 for a vertical tube. The most important mechanisms are nucleate boiling (subcooled and saturated), evaporation, and film boiling. In *nucleate boiling,* wall conditions are such that the vapor bubbles start in the liquid at the nucleation sites on the wall of the heated tube. Usually, the wall superheat (i.e., the wall temperature minus the saturation temperature of the liquid) is large, the liquid film thickness is also large, and vapor mass is low in nucleate boiling. Depending on whether the liquid is subcooled or saturated, it is referred to as subcooled or saturated nucleate boiling. Bubble, slug, and plug flow patterns exist during nucleate boiling. When the liquid film near the wall is thin, and the wall superheat is relatively low, no nucleation occurs at the wall. Heat is carried away from the wall by forced convection in the film to the liquid film – vapor core interface where evaporation occurs. Since the nucleation is completely suppressed, the phenomenon can no longer be called "boiling". The *evaporation* region is also referred to as the two-phase forced convective region. The vapor volume is usually high in this region with the quality ranging from 0.2 to 0.6. Annular and mist annular flow exist during evaporation. This is the most important region for the design of evaporators. If the temperature difference exceeds the critical temperature difference, a continuous vapor film then blankets the tube wall and results in a significant decrease in the heat-transfer rate. This phenomenon is referred to as *film boiling.* For nuclear reactor fuel elements, radiantly heated furnaces, and other applications for which the heat flux is an independent variable, there will be a sharp increase in the wall temperature as the critical heat flux value is reached. This could burn out the tubes. Film boiling should be avoided in the design of heat-transfer equipment.

Figure 44. Heat-transfer regions in convective boiling

Saturated flow boiling is referred to as the region of two-phase flow where the liquid is at its saturation temperature. This would include both saturated nucleate boiling and evaporation mechanisms and will encompass bubble, slug, plug, churn, annular, and annular mist flow regimes. Specific design correlations are summarized in this chapter for saturated flow boiling and critical heat flux for vaporization in tubes and over tube bundles. Correlations for other flow regimes and further details are given in [92], [93].

7.4.1. Intube Forced Convective Boiling

The vaporization of a liquid flowing inside a tube is a complex process. Typical flow patterns for vaporization in vertical tubes are shown in Figure 44. Similarly, the flow patterns in horizontal tubes are given in [60] among others. Of the various flow regimes shown, the most important regime is the annular which exists for 80 – 90 % of the tube length.

Saturated flow boiling refers to both nucleate boiling (dominant at low qualities) and evaporation (dominant at high qualities) processes. In 1966, Chen [94] was the first to correlate the heat-transfer coefficients for saturated flow boiling in a vertical tube. He conjectured that the microconvection of nucleate boiling and macroconvection of single-phase heat transfer are additive, and that the contributions of one mechanism over the other is dependent on the two-phase Reynolds number. During the last 21 years, many attempts have been made to refine

Table 18. Constants in the saturated flow boiling correlation of Equation (124)

	$Co < 0.65$ Convective region	$Co > 0.65$ Nucleate boiling region
c_1	1.1360	0.6683
c_2	− 0.9	− 0.2
c_3	667.2	1058.0
c_4	0.7	0.7
c_5	0.3	0.3
$c_5 = 0$ for vertical tubes and for horizontal tubes with $Fr_l > 0.04$		

Table 19. Fluid dependent parameter F_{fl} of Equation (124)

Fluid	F_{fl}
Water	1.00
R-11	1.30
R-12	1.50
R-13B1	1.31
R-22	2.20
R-113	1.10
R-114	1.24
R-152 a	1.10
Nitrogen	4.70
Neon	3.50

this correlation which is valid for many different fluids [61], [95]. One of the most accurate correlations, based on 5246 data points of ten fluids, is given in [95]. The local two-phase heat-transfer coefficient is correlated as

$$\frac{h_{tp}}{h_l} = c_1 Co^{c_2} \left(25 Fr_l\right)^{c_5} + c_3 Bo^{c_4} F_{fl} \tag{124}$$

where

$$h_{tp} = q'' / \left(T_w - T_{sat}\right) \tag{125}$$

$$h_l = 0.023 Re_l^{0.8} Pr_l^{0.4} \left(k_l / d_i\right) \tag{126}$$

$$Co = \left(\frac{1-x}{x}\right)^{0.8} \left(\frac{\varrho_g}{\varrho_l}\right)^{0.5} \tag{127}$$

Co = Convection number

$$Fr_l = \frac{G^2}{g d_i \varrho_l^2} \tag{128}$$

Fr_l = Froude number with all flow as liquid

$$Bo = q'' / \left(G i_{lg}\right) \tag{128a}$$

Bo = Boiling number

Constants $c_1 - c_5$ are given in Table 18, the fluid-dependent parameter F_{fl} is given in Table 19, and Bo is defined in Equation (130). For fluids other than those listed in Table 19, F_{fl} could be estimated by the method given in [96].

The correlation in Equation (124) is applicable to vertical upflow and downflow, and horizontal flow. It was used to correlate water data with a mean deviation of ± 16 % and all refrigerant data with a mean deviation of ± 19 %.

7.4.2. Intube Critical Heat Flux

The prediction of critical heat flux (CHF) is of great practical importance in design and analysis of heat-transfer equipment. Either the heat-transfer coefficient and rate could decrease sharply and/or the tube wall temperature could increase sharply with a possible catastrophic failure. Many of the investigations have centered on the critical heat flux for the uniformly heated vertical tubes. Many literature reviews have been published on the subject to scrutinize an estimated 200 – 400 correlations [61], [97]. The most accurate and versatile correlation is by Shah [97] which is based on the test data of 23 fluids from 62 sources. It is derived for vertical upflow with uniform heat flux condition. It would also be applicable to vertical downflow and horizontal flow as long as a high flow rate is maintained. This correlation predicts q_{cr} for all test data with a mean deviation of ± 16 %. This correlation consists of two subcorrelations: the first one depends upon the upstream conditions (inlet subcooling and distance from inlet); the second depends upon the local quality, except for very short tubes. The correlations are presented first followed by the procedure to use them.

The upstream condition correlation is given by

$$Bo = 0.124 \left(\frac{d_i}{L_{ef}}\right)^{0.89} \left(\frac{10^4}{Y}\right)^n \left(1 - x_{i,ef}\right) \tag{129}$$

where

$$Bo = q''_{cr} / \left(G i_{lg}\right) \tag{130}$$

$$Y = Pe_l Fr_l^{0.4} \left(\mu_l/\mu_g\right)^{0.6}, \; Pe_l = G d_i c_{p,l}/k_l \tag{131}$$

$$n = \begin{cases} 0 & \text{for all fluids with } Y \le 10^4 \\ (d_i/L_{ef})^{0.33} & \text{for helium with } Y > 10^4 \\ (d_i/L_{ef})^{0.54} & \text{for all other fluids with } 10^4 < Y \le 10^6 \\ 0.12/(1 - x_{i,ef})^{0.5} & \text{for all other fluids with } Y > 10^6 \end{cases} \tag{132}$$

$$L_{ef} = \begin{cases} L_{cr} & \text{for } x_i \le 0 \\ L_b & \text{for } x_i > 0 \end{cases} \tag{133}$$

$$x_{i,ef} = \begin{cases} x_i & \text{for } x_i \le 0 \\ 0 & \text{for } x_i > 0 \end{cases} \tag{134}$$

Here L_{ef} is the effective length of the tube and $x_{i,ef}$ is the effective quality. L_{cr} is the axial distance from the tube inlet to the location x_{cr} of the critical heat flux. L_b is the boiling length, or the axial distance between $x = 0$ and x_{cr}, and is given by the following expression for uniformly heated tubes:

$$\frac{L_b}{d_i} = \frac{x_{cr}}{4Bo} = \frac{L_{cr}}{d_i} + \frac{x_i}{4Bo} \tag{135}$$

The local condition correlation is given by

$$Bo = F_e F_x Bo_o \tag{136}$$

where

$$F_e = \max\left[1, 1.54 - 0.032\left(L_{cr}/d_i\right)\right] \tag{137}$$

$$F_x = \begin{cases} F_3 \left[1 + \frac{\left(F_3^{-0.29} - 1\right)(p_r - 0.6)}{0.35}\right]^c & \text{for } x_{cr} > 0 \\ F_1 \left[1 - \frac{(1 - F_2)(p_r - 0.6)}{0.35}\right]^c & \text{for } x_{cr} < 0 \end{cases} \tag{138}$$

$$c = \begin{cases} 0 & \text{for } p_r \le 0.6 \\ 1 & \text{for } p_r > 0.6 \end{cases} \tag{139}$$

$$F_3 = \left(\frac{1.25 \times 10^5}{Y}\right)^{0.833 x_{cr}} \tag{140}$$

$$F_1 = \begin{cases} 1 + 0.0052\left(-x_{cr}^{0.88}\right) Y^{0.41} & \text{for } Y \le 1.4 \times 10^7 \\ 1 + 4.425\left(-x_{cr}^{0.88}\right) & \text{for } Y > 1.4 \times 10^7 \end{cases} \tag{141}$$

$$F_2 = \begin{cases} F_1^{-0.42} & \text{for } F_1 \le 4 \\ 0.55 & \text{for } F_1 > 4 \end{cases} \tag{142}$$

$$Bo_o = \max\left[15 Y^{-0.612}, \; 0.082 Y^{-0.3}\left(1 + 1.45 p_r^{4.03}\right), \; 0.0024 Y^{-0.105}\left(1 + 1.15 p_r^{3.39}\right)\right] \tag{143}$$

Here the function max means the maximum value of 2 or 3 quantities within the brackets.

The choice between Equation (129) and (136) is made as follows:

Always use equation (129) for helium
For $Y \le \pi\, 10^6$, use Equation (129) for all other fluids
For $Y > \pi\, 10^6$, and $L_{ef} > 160/p^{1.14}$, use Equation (129) for all other fluids
For $Y > \pi\, 10^6$ and $L_{ef} < 160/p_r^{1.14}$, determine *Bo* from Equations (129) and (136), and use the lower value.

7.4.3. Shellside Forced Convective Boiling

Heat-transfer coefficients for forced convective boiling over a tube bundle are significantly higher than those for a single tube due to circulation and turbulence caused by the rising vapor bubbles. Nucleation and convection govern the heat-transfer behavior of boiling in a tube bundle. Convection effects are important at low heat fluxes and low pressures, and nucleation effects dominate at high heat fluxes and high pressures. Increasing quality adds to the convective effects only at low heat fluxes and mass velocities. The heat-transfer coefficient increases with increasing mass velocity, but is insensitive to the quality. It is dependent upon the clearance between the tubes, but not so dependent upon the tube layout, staggered or inline. Within limits, the heat-transfer coefficient increases with increasing height in the bundle [77]. In large bundles, the upper tubes may be starved of liquid.

Because of the trade-off between nucleation and convective effects, many attempts have been made in literature to devise a Chen-type correlation. These efforts have been summarized in [77], [79], [98]. They conclude that the Chen-type correlation is not quite accurate for the tube

bundle since the whole tube surface is not swept by the flow, and the form drag effects over tubes are present which were not considered with the two-phase friction multipier in the original Chen formulation. JENSEN [77] recommends to use the Chen-type correlation until a better technique is developed with an accuracy of the order of $\pm 40\,\%$; one such correlation is given in [79], [98]. Another correlation is given later by Equation (160).

7.4.4. Shellside Critical Heat Flux

Critical heat flux for a tube bundle immersed in a pool is considerably lower than that for a single tube in pool boiling. The pool boiling curve for a tube bundle has a flat plateau at the maximum heat flux in contrast to a peak for the single tube. The critical heat flux condition for the tube bundle is defined as the condition when the integrated effect of all tubes begins to adversely affect the tube bundle performance. Different tubes in a bundle reach the critical heat flux condition at different times. Increasing the temperature driving force yields higher heat-transfer coefficients on those tubes that have not yet reached the CHF condition, and are counterbalanced by lower heat-transfer coefficients on the CHF-affected tubes [77]. Only a very limited amount of data are available in literature for the tube bundle CHF. Hence, no generalized accurate correlation can be recommended. Palen and Small's [99] correlation for the CHF is often quoted and is conservative; it is given by Equation (166).

8. Thermal Design for Single-Phase Heat Exchangers

Two of the most common heat-exchanger design problems are the rating and sizing.

The *rating problem,* also referred to as the performance problem, is analyzed for predicting the performance of an exchanger which has already been built or designed. The objective here is either to verify the manufacturer's specifications or to determine the performance at off-design conditions. The following quantities need to be specified: the exchanger construction type, flow arrangement, overall core dimensions, complete details on the material and surface geometries on both sides including their heat-transfer and pressure-drop characteristics, fluid flow rates, inlet temperatures, and fouling factors. The designer's task is to predict the fluid outlet temperatures, heat-transfer rate, and pressure drop on each fluid side.

The *sizing problem*, also referred to as a design problem, involves the design of a new heat exchanger for a specified performance within known constraints and maximum/minimum objective function. In this problem, the fluid inlet and outlet temperatures and flow rates are generally specified as well as the pressure drop on each fluid side. The designer's task is to select the appropriate construction type, flow arrangement, materials and surfaces on each side, and to determine the exchanger dimensions to meet the required heat transfer and pressure drop.

Computers are widely used to perform the exchanger rating and sizing calculations. Many proprietary programs of varying accuracy and usefulness are available. Major computer programs for shell-and-tube exchangers are summarized in [100]. The better programs are those supported by research organizations specializing in the field. The output of any computer program needs to be carefully analyzed especially if used in the design mode, since its internal logic affects the final design.

Very detailed step-by-step solution procedures are presented for plate – fin and tube – fin single-phase exchangers in [101], for plate exchangers in [3], for regenerators in [102], and heat pipe heat exchangers in [6]; hence, they are not covered here. In shell-and-tube exchangers, various leakage and bypass streams would affect both the heat-transfer coefficient and pressure drop on the shell side.

8.1. Introduction

Tubeside flow is through straight or U tubes. Hence, the correlations given in Chapter 7 on heat-transfer coefficients and friction factors for circular tubes are applicable. For U tubes, pressure drop associated with a 180° bend should be included in the analysis. For multipass exchangers, allowance must be made for the turnaround losses in the front and/or rear end heads.

In contrast, the shellside fluid flow is very complicated. It is a function of the type of baffling used, i.e., segmental, disk-and-doughnut, rod, etc., which will determine the method of design and the specific heat-transfer and pressure-drop correlations to be used. Segmental baffles are the type most widely used, especially in the United States, and have been extensively researched. Disk-and-doughnut baffles are reported to be frequently used in Europe but the design correlations are based on limited data. The rod baffling is a patented design and other similar designs are also available, but design data are again limited with respect to quantity and sources.

8.2. Shell-and-Tube Exchangers

8.2.1. Segmental Baffles

The segmental baffle is formed from a circular disk by cutting off a segment which is in the range of 0.2 – 0.45 of its diameter. These baffles are placed so that the cut segment is on alternate ends, thus causing the fluid to flow at approximately 90° to the tube bundle. Manufacturing clearances and tolerances are required for an assembly of the exchanger; they provide paths for the fluid to leak past the baffle thus reducing the fluid flowing across the bundle. The tube bundle does not completely fill the shell thus some fluid bypasses the bundle by flowing through the clearance between the shell and the bundle outside diameter. This clearance is a function of the rear-end head design. Figure 45 shows these leakage and bypass flow streams as originally described in [103] and later modified in [104] for a segmentally baffled exchanger. Various streams are described in order of decreasing thermal effectiveness as follows:

B Stream: Crossflow stream flowing over the tubes (and fins if any) between successive windows. This stream is considered fully effective for both heat transfer and pressure drop.

A Stream: Tube-to-baffle hole leakage stream through the annular clearance between the tubes and the baffle holes of a baffle. This stream is created by the pressure difference on the two sides of the baffle. As heat-transfer coefficients are very high in the annular spaces, this stream is considered fully effective.

C Stream: Bundle-to-shell bypass stream through the annular spaces (clearances) between the tube bundle and shell. It flows between successive baffle windows. This stream is only partially effective for heat transfer as it contacts only those tubes near the circumference.

E Stream: Shell-to-baffle leakage stream through the clearance between the edge of a baffle and the shell. This stream is the least effective for heat transfer because it may not come in contact with any tubes (i.e., heat-transfer surface area).

Figure 45. Various flow streams for shellside flow

F Stream: Tube-pass partition bypass stream through open passages created by tube layout partitions (when placed in the direction of the main crossflow stream) in a multipass unit. This stream is less effective than the A stream because it comes into contact with less heat-transfer area per unit volume; however, it is slightly more effective than the C stream.

Based on extensive test data for well-designed exchangers, Taborek [105] reported flow fractions for various streams as shown in Table 20. It is surprising to note from this table that the B stream may represent only 25 % of the total flow for some exchangers in laminar flow. Hence, the predicted performance based on the

conventional LMTD method will not be accurate in general. As a result, there is no need to compute very accurate values of F factors for various exchanger configurations.

Table 20. Flow fractions for various shellside flow streams [105]

Stream	Turbulent	Laminar
Main cross flow (B)	40 – 70 %	25 – 50 %
Bundle bypass (C + F)	15 – 20 %	20 – 30 %
Shell-to-baffle leakage (E)	6 – 20 %	6 – 40 %
Tube-to-baffle leakage (A)	9 – 20 %	4 – 10 %

By defining the pressure drops across the various leakage and bypass paths, TINKER [103] determined the amount of fluid flow in each path by a pressure balance analysis. This calculation procedure is best done with computers since iterations are required as the fluid physical properties influence the flow resistance values of the several paths. Tinker's basic method has been modified and improved, and is used in the better proprietary computer programs.

8.2.1.1. Shellside Heat Transfer

All methods use heat transfer in ideal tube data banks as a basis. An ideal tube bank is a specially designed rectangular bank having no leakage or bypass streams. The fluid velocity is based on the minimum area between tubes which is a function of the tube layout, triangular or square. For circular shells, the velocity is based on the minimum area at the shell diameter.

The best method to predict the shellside heat-transfer coefficient is given in [106], referred to as Bell – Delaware method. The heat-transfer coefficient h_{id} for the ideal crossflow is modified by five correction factors as follows.

$$h_s = h_{id} J_c J_l J_b J_s J_r \tag{144}$$

where

h_{id}= coefficient for pure crossflow in an ideal tube bank assuming the entire shellside stream flows across the tube array at the centerline of the exchanger.

J_c= correction factor for the baffle cut. This correction includes the effect of window and bundle heat transfer. Its value is 1.0 for an exchanger with no tubes in the window and increases to 1.15 for small baffle cuts and decreases to 0.65 for large baffle cuts. For a typical well-designed heat exchanger, its value is near to 1.0.

J_l= correction factor for baffle leakage effects including both tube-to-baffle and baffle-to-shell leakage (A and E streams) with a heavy weight given to the latter. It is a function of the ratio of leakage area to crossflow area and a function of the clearances. A typical value of J_l is in the range of 0.7 – 0.8.

J_b= correction factor for bundle bypass (C and F stream). For a fixed tubesheet construction, $J_b \approx 0.7$, which can be increased to approximately 0.9 by the use of side strips.

J_s= correction factor for baffle spacing at the inlet and outlet sections. The nozzle locations result in larger baffle spacing and lower velocities and thus lower heat-transfer coefficients. J_s usually ranges from 0.85 to 1.0.

J_r= correction factor for any adverse temperature gradient buildup in laminar flows. This correction applies only for shellside Reynolds numbers < 100.

The calculation of these factors requires determination of leakage and bypass areas and involves considerable calculations best done with the aid of computers. Refer to [26], [105], [106] for manual determination of these factors. In a well-designed exchanger, the product of five correction factors is ca. 0.6, but can be as low as 0.4 [106].

The leakage between the baffle and shell (E stream) and the bypass stream between the bundle and shell (C stream) both tend to bypass the heat-transfer surface, and thus affect the effective temperature difference in the exchanger. Based partially on theory and experimental data, some proprietary programs have an additional empirically-derived correction factor that is applied to the log-mean temperature difference. Based on the model of some mixing within the shell, FISHER and PARKER [107] have presented a few of the many possible charts for the temperature difference correction factor F for multipass shell-and-tube exchangers. They show a significant effect on the number of baffles and the bypass ratio especially for less than 16 baffles.

The best predictions are totally computer dependent; they involve the use of a stream analysis method [100], [104] to determine the actual flow through the tube bundle which is then used with ideal tube bank data to determine the heat-transfer coefficient.

8.2.1.2. Shellside Pressure Drop

The pressure drop evaluation on the shell side of a segmentally baffled heat exchanger is complicated due to the presence of bypass and leakage streams in addition to the crossflow stream. Basically, the pressure drop is evaluated first for an ideal crossflow section and an ideal window section. Correction factors are then applied for the leakage and bypass streams. The total pressure drop is then the sum of the pressure drops for each window section and each crossflow section. Excluding the pressure drop associated with the nozzles, it is given by

$$\Delta p_s = \Delta p_c + \Delta p_w + \Delta p_e \tag{145}$$

where Δp_c = pressure drop associated with crossflow zones

$$\Delta p_c = \Delta p_{b,id}\,(N_b - 1)\,R_l R_b \tag{146}$$

Δp_w = pressure drop associated with window zones

$$\Delta p_w = N_b \Delta p_{w,id} R_l \tag{147}$$

Δp_e = pressure drop associated with end (inlet and outlet) sections

$$\Delta p_e = 2\Delta p_{b,id}\left(1 + \frac{N_{cw}}{N_c}\right) R_b R_s \tag{148}$$

Here N_b is the number of baffles, N_c is the number of tube rows in one crossflow section (between baffle tips), and N_{cw} is the number of effective crossflow rows in each window. $\Delta p_{b,id}$ and $\Delta p_{w,id}$ are ideal pressure drops in crossflow and window zones, respectively. The correction factors are defined as:

R_l = correction factor for leakage (A and E) streams. This factor is based on the same factor as J_l but is of different magnitude. Usually $R_l \approx 0.4 - 0.5$ although lower values are possible with small baffle spacing.

R_b = correction factor for bypass flow (C and F) streams. It is different in magnitude from J_b and ranges from 0.5 to 0.8.

R_s = correction factor for inlet and outlet sections having a baffle spacing different from the central section.

Specific values of these correction factors and the computation of ideal crossflow and window zone pressure drops are dealt with in [26], [105], [106].

8.2.2. Disk-and-Doughnut Baffles

The disk-and-doughnut baffles as shown in Figure 26 consist of an alternating series of doughnuts followed by disks with a diameter larger than the doughnut hole. Fluid flows in radially toward the hole, then radially out to the annular space between the disk and the shell. While there is leakage through the clearances between the tube and baffle and the baffle and shell, there is no bypass stream such as the C stream designated by Tinker (Fig. 45). This baffle has better thermal performance per unit pressure drop compared to the segmental baffle due to the absence of the bypass stream C. No research has been reported on the effect of the leakage streams on the heat-transfer and pressure-drop performance of this baffle. Only limited design information is available on this type of baffle [108–112].

8.2.3. Rod Baffles

The rod baffle consists of parallel spacer rods or bars welded to a closely fitted baffle ring as shown in Figure 27. A series of these baffles are rotated to support the tubes on several sides depending on the type of tube layout used. The fluid flows parallel to the tubes except at the ends when entering and leaving the bundle. There are no leakage areas between tubes and baffles but there is a bypass between the bundle outside diameter and shell that passes through the clearance between the baffle ring and shell. Some design data for rod-baffled exchangers are given in [113].

8.2.4. Design Procedure

The solution to the rating problem for a shell-and-tube exchanger is straightforward once all necessary input data are known and the influences of leakage and bypass flow are properly evaluated. The solution to the sizing problem is done iteratively and the steps required for design are as follows:

1) Calculation of the required duty
2) If not already specified, determination of the unknown temperatures or fluid flow rates
3) Estimation of an overall coefficient based on experience, from tables such as Table 21, or estimate the individual coefficients and then calculate the overall coefficient
4) Calculation of the heat-transfer surface area
5) Based on the heat-transfer surface area, flow rates, and process conditions, selection of a suitable type of exchanger
6) For a multipass shell-and-tube exchanger, determination of the correction factor *F,* and whether or not multiple shells are required
7) Selection of tube size, pitch, and layout
8) Selection of tubeside fluid. Selection of number of passes, shell size, and baffle spacing
9) Proceeding to the rating calculations, evaluation of the results, modification of the design and reiteration of these calculations until an acceptable design is obtained.

More detailed solution procedures to the rating and sizing problems are presented in [26], [105] and [106].

9. Thermal Design for Multiphase Heat Exchangers

9.1. Condensers

9.1.1. Considerations in Condenser Design

The principal factors involved in selecting a suitable type of condenser depends on whether condensation is total or partial, whether the vapors are single or multicomponent, and whether some components are noncondensable. The coolant can impose further restrictions, particularly if it vaporizes. The additional requirement for condensate subcooling or the need for vapor–condensate contact within the condenser also influences the condenser type.

The decision of tubeside, shellside, or direct contact condensation depends on the following factors in addition to those discussed in Section 4:

1) *Freezing.* If the condensate can freeze, shellside condensation with large tube pitches is preferred as it is less susceptible to plugging.
2) *Condensate control.* When condensing multi-component mixtures having a substantial boiling or dew point range, or when there are soluble gases present, it is necessary to control the condensate and vapor flow so as to enable the low boilers to condense, or to prevent their condensation or absorption when stripping. The best control is with tubeside condensation, since on the shellside the condensate can drop away from the cooling surfaces. For good condensate drainage, sufficient flow area should be provided at the condensate nozzle; so that the tube bundle does not block the nozzle opening.
3) *Noncondensables.* The accumulation of a small percent of noncondensable gases in condensers can significantly reduce the condensing coefficients. Venting for in-tube condensation is simple as the flow path is fixed; however, for shellside condensation, the gases can segregate in pockets at the cold end, and are difficult to remove unless sufficient pressure drop (vapor velocity) is used to force these gases to the vent outlet. The venting problem is most severe in the typical crossflow condenser with either horizontal or vertical tubes. Some studies on venting are presented in [114–116].

9.1.2. Condenser Types and Their Characteristics

9.1.2.1. Shellside Condensers

Horizontal Tubes. Horizontal condensers can be baffled or crossflow in design. Baffles and/or support plates are usually arranged with vertical cuts, thus causing the vapor to flow from side to side. A horizontal cut is occasionally used under special conditions.

Table 21. Range of overall heat-transfer coefficients in two-fluid heat exchangers [26]

Hot fluid	Cold fluid	Overall heat-transfer coeffcient	
		Btu/h · ft^2 · °F	W/m^2 · K
	Coolers		
Water	water	250 – 500	1220 – 2440

[c] Viscosities > 1.0 centipoise ($= 1.0$ m Pa s)
[d] Pressure drop 20 – 30 lbf/in^2 ($= 9 - 13.6$ kg/2.5×10^{-2} m)
[e] These rates are influenced by operating pressures [26]

The lower edges of the baffles are notched to permit draining. The baffle spacing may be made variable if a high vapor velocity needs to be maintained, such as when noncondensables are present. A few close-spaced baffles near the vent gas outlet will promote cooling of these gases. Side-strip baffles are desirable, especially when condensing mixtures, but are also useful with single vapors to improve venting. A significant amount of vapor can bypass the bundle even with modest clearances. With the impingement plate partially blocking the vapor from entering the bundle, it is important to allow sufficient clearance around the edges to reduce pressure drop and possible tube vibration. If the pressure drop becomes limiting, then double segmental baffles, split-flow (J shells), or crossflow (X shells) are used.

For partial condensation of a wide-boiling-range mixture, vertical baffle cuts are acceptable if the flow pattern is maintained in the spray region. A horizontal baffle cut allows the vapor condensate mixture to flow up and down and will give good contact between the vapor and condensate, but requires high pressure drop and a spray flow pattern. The shellside horizontal condenser is an unacceptable design for total condensation of a wide-boiling-range mixture, especially if the dew-point temperature of the lowest-boiling component approaches the temperature of the coolant discharge.

Low (1 – 2 mm) fin tubes are often used in horizontal shellside condensers when the condensing coefficient is low; e.g., refrigerants. The surface tension of the condensate must be low ($< 4 \times 10^{-4}$ N/cm or 40 dynes/cm); otherwise,

the condensate will fill the fins, resulting in loss of effective surface and capacity.

Subcooling is sometimes attempted by partially flooding the condenser with a dam or using an external level control in order to establish a cooling zone. However, the pressure gradient within the shell will affect the actual liquid levels, and hence, the cooling area.

The advantages of horizontal shellside condensers are that the pressure drop can be kept low and the fouling fluid is on the tube side. The tube side can be multipassed to improve its coefficients, reduce fouling, and obtain greater temperature rises. The baffle spacing can be varied to maintain vapor velocities. Finned and enhanced tubes are available for improving heat transfer and reducing size.

The disadvantages are high shell cost if alloy or high-pressure shells are required. Subcooling is poor and not predictable. Venting of crossflow shells is a problem. The vapor and condensate tend to separate and stratify, thus creating a problem in condensing wide-boiling-range mixtures. Tube vibration may occur, and providing adequate supports may be difficult.

Vertical Tubes. Condensation outside of vertical tubes is most often encountered in vaporizers and heaters. The shell side can be baffled, but most often only support plates are used. If the shell is baffled, condensation coefficients are calculated using the same equations as for a horizontal baffled condenser. For unbaffled shells or with support plates, the conservative approach is to ignore the effect of velocity and the effect of the support plate in removing the condensate.

Vertical shell side condensers normally have downflow of vapor. An upflow is rarely used, and if used, should not have any baffles or support plates.

9.1.2.2. Tubeside Condensers

Horizontal Tubes. Horizontal in-tube condensers are made in single, multipass, and U-tube arrangements and in a wide range of tube sizes and lengths. Tube layouts are governed by the coolant requirements. With straight-tube multipass arrangements, the succeeding passes should be below one another (vertically downward). The condensate drop-out between passes will cause maldistribution, and its effect on the condensation process must be considered.

Vapors enter the tubes at high velocity, and the initial condensate is an annular film. If the shear rate is high enough, some condensate may be ripped off the walls and is entrained as a mist. As condensation proceeds, the ratio of condensate to vapor increases and a thick layer of condensate builds up on the tube bottom. Waves will form due to vapor shear and can become high enough to reach the top of the tube, thus forming slugs of vapor and condensate. Under some conditions, these slugs may stop and reverse direction temporarily, thus causing an unsteady or oscillating flow. Finally, as the vapor velocity approaches zero, the condensate will drain from the tube under its hydrostatic head. For large amounts of condensate, the tube may become completely filled, but this condition should be avoided since, as mentioned above, the oscillations may become violent and have been known to destroy tube bundles. Thus, the important key to both heat transfer and pressure drop is the flow pattern.

Horizontal in-tube condensers are most commonly employed as air-cooled condensers. These condensers need little head room, but much floor space. However, they are useful in partial condensation with noncondensables since the path length can be made longer by multipassing, the velocities can be kept up by reducing the number of tubes per pass, and the condensate can drop out between passes to travel in separate lower tubes, thus reducing pressure drop. In this case, the condensate and vapor contact is poor; therefore, the arrangement is unsuitable for total condensation of wide-boiling-range mixed vapors. Subcooling is poor, as the condensate only partially fills the tube. Most condensers are single pass, but two-pass and U-tubes are very common. More than two passes is unusual.

Vertical Tubes – Downflow. A vertical downflow condenser is shown in Figure 46 as a shell-and-tube unit with an outside packed head and a separating head. A fixed tubesheet construction can be used if shellside cleaning is unnecessary or can be done chemically. The space between the upper tubesheet and the up-

per shell nozzle can entrap air; therefore, special vents are drilled into the upper tubesheet and arranged to discharge continuously into an open drain. This assures that the tubesheet is wetted and cooled, and that the water is kept from stagnating, thus reducing fouling and corrosion at the air – water interface. The lower separating head has either a funnel or a baffle designed to minimize reentrainment of condensate into the vent gas stream. The condensate level is kept below the baffle or funnel.

Figure 46. In-tube vertical downflow condenser
a) Tube sheet vent; b) Packed head; c) Slip-on flange with split ring; d) Baffle plate separating head; e) Vapor vent; f) Funnel separating head; g) Alternate head

The vapor enters the top head usually through a radial nozzle, although an axial nozzle can also be used. For axial nozzles, the nozzle entrance velocity head pressure should be very low compared to the condenser tube pressure drop to ensure that maldistribution is not severe. If needed, a perforated impingement with 5 – 10 % hole area placed 0.5 – 1.0 nozzle diameter downstream will help.

The vapors condense on the tube wall as an annular film and drain to the bottom. Tube diameters are usually 19 or 25 mm, although for low pressures larger tubes up to 50 mm are used to reduce pressure drop. Occasionally small diameters of 16 mm are used. At the end of the condensing zone, there is a vapor – noncondensable gas interface, and below this interface the condensate is subcooled as a falling film. As the load on the condenser varies, the vapor – gas interface (and hence, the ratio of condensing to subcooling lengths) will change. System pressure control is obtained by controlling the vent gas pressure. If the noncondensable gases in the incoming vapor are insufficient to maintain pressure control for a reduction in load, then an innert gas is bled in for pressure operation, or air is bled into the vacuum line for vacuum operation. For atmospheric operation, the vent line exhausts to a stack.

It is possible to operate without the inert gas by flooding the bottom of the tubes; however, this is not recommended because (1) subcooling is poorer; (2) there is no venting, and noncondensables can accumulate and reduce condensing and/or subcooling capacity; (3) pressure control is more difficult; and (4) there is a possibility of a slugging effect.

The shellside is baffled, and the coolant flows in a single pass countercurrent to the vapor. If control of the condensate temperature is necessary, a cocurrent flow of the coolant will give better subcooling control, but more coolant may be used.

There are many advantages to the vertical downflow condenser as the condensate is always in contact with a cold wall and with the vapors, thus promoting the condensation of low boilers from a wide-boiling-range mixture. The condensate washes all the surfaces, which is an advantage under certain corrosive conditions. Sprays can be readily placed in the upper head to supply additional liquid for absorption of low boilers or to aid in washing the tubes when condensing dusty vapors. The vapor flow path is well defined, and venting of noncondensables is positive. The subcooling coefficients are high and predictable.

The disadvantages are that the coolant, which may have a greater fouling tendency, is on the shell side and may require a packed head design as well as the need for a continuous vent through the tubesheet. At low absolute pressures

(< 3.3 kPa or 25 mm Hg), the tubeside pressure drops become high and require use of large (38 – 50 mm) tubes in order to have a reasonable condensing length.

Vertical Tubes – Upflow. A typical in-tube vertical condenser with vapor flowing upward and the condensate returning by gravity is called a *knockback* or *reflux condenser*. Special features are that the lower ends of the tubes that extend beyond the bottom tubesheet are cut at an angle of about 60 – 75 degrees to provide drip points for the returning condensate. The shellside should be vented through the upper tubesheet. Depending on coolant fouling characteristics, a fixed or removable bundle can be used. Vapors enter the bottom head through a radial nozzle, but frequently the condenser sits directly on top of the distillation column without a nozzle. Reflux condensers usually are short (2 – 3 m) with large diameter (≥ 25 mm) tubes.

Reflux condensers are used principally when a hot condensate return is necessary and when small amounts of low-boiling components are to be stripped out or prevented from condensing. However, the high boilers entering the condenser will raise the condensing temperature and may thus avoid the use of low-temperature coolants. The effectiveness of separation is not as good as the addition of more packing or plates in a distillation tower with a product take-off below the top plate. As pointed out in [117], it is not possible to specify fractionation, heat requirements, and coolant temperatures independently, because only two of the three can be selected arbitrarily. Also, as shown in [118], the fractionation is affected by throughput rate. Based on a number of simplifying idealizations, TROSTER [118] suggested a two-part approach to the design of reflux condensers.

The major disadvantage is the capacity limitation due to flooding. Flooding occurs when the upward vapor velocity prevents the free return of condensate and the tubes periodically load with condensate and then dump it. At higher velocities, all the condensate can be blown out of the top of the condenser, but then only a small fraction of vapor is condensed. Because of the relatively low velocities in a reflux condenser, they are not suitable for condensation of mixtures containing large amounts of noncondensable gases.

A number of studies have been made on flooding velocities in tubes resulting in different equations or graphs. The English et al. [119] equation below gives results close to HOLMES's [120] curves for beveled tubes.

$$G_{\mathrm{f}} = \frac{80 d_{\mathrm{i}}^3 \varrho_{\mathrm{l}}^{0.46} \sigma_{\mathrm{l}}^{0.09} \varrho_{\mathrm{g}}^{0.5}}{\mu_{\mathrm{l}}^{0.14} (\cos\theta)^{0.32} \Lambda^{0.07}} \tag{149}$$

Here, G_{f} is the mass velocity at the start of flooding (kg m^{-2} s^{-1}), d_{i} is the tube *ID* (mm), ϱ_{l}, ϱ_{g} are densities (kg/m^3), σ_{l} is the surface tension (dynes/cm), μ_{l} is the dynamic viscosity (cP), θ is the taper of the tube end from horizontal (degrees), and Λ is the weight ratio of condensate to vapor at the bottom of the tube. Flooding correlations are reviewed in [121].

9.1.2.3. Air-Cooled Condensers

An air-cooled condenser consists of a shallow bank of finned tubes with the condensing vapor inside the tubes frequently in a single-pass arrangement. With a uniform distribution of vapor, the condensing length of the first tube row is considerably shorter than in the last tube row. As pointed out in [122], any excess vapor leaving the last tube row will not backflow into the first row due to the accumulation of noncondensable gases at the end of the condensing zone. A number of methods to reduce the backflow and inert gas blanketing in these condensers are reviewed in [123].

Air coolers are designed on an air temperature that is usually exceeded by only 2 – 5 % of the annual hours based on the recorded daily temperatures of the plant (or closest weather station). The condenser will have excess capacity for > 90 % of the time; hence, few additional safety factors, other than allowances for fouling, are added to the theoretical surface.

The air face velocity ranges from 2 to 4 m/s (6 – 12 ft/s) depending upon the number of tube rows and fan design. The fan is designed to handle large volumes of air at pressure drops of approximately 200 – 300 Pa (0.8 – 1.2 in H_2O) and its speed is limited by the noise it generates.

Either forced or induced draft coolers are used depending on the local preference or the designer's judgement of the relative advantages and disadvantages of these types. For forced

draft, the fan is in the cool inlet air resulting in better fan performance and heat-transfer coefficients. However the upper exposed tube bundle is more susceptible to sun, wind, or rain, and control of condenser pressure can be more difficult. Induced draft, with its high discharge velocity avoids air recirculation problems and is less influenced by surrounding buildings. Air coolers must be carefully integrated with the plant layout of buildings and equipment, and prevailing winds, otherwise the performance will suffer. The cooler must also be designed for, and be capable of operating over, the full range of air temperatures. Further details are given in [10].

9.1.3. Condensation of Mixtures

The two classes of mixtures are: (1) mixtures in which some of the components are not condensable, and (2) mixtures that are totally condensable or where the low boiling components are soluble in the condensate. Each is a nonisothermal condensation process and has a vapor-phase diffusional resistance. Design equations for binary mixtures have been developed but approximate design methods are used for more complex mixtures, as the theories of complex mixtures are too cumbersome.

For a mixture with a noncondensable gas the Colburn – Hougen [124] equation is used to find the heat flux at a given point along the condenser:

$$U'(T_i - T_c) = h'_g (T_v - T_i) + K_m i_{lg} (p_v - p_i) \tag{150}$$

where U' = the overall coefficient from the condensate interface to the coolant, and

$$h'_g = \left(\frac{a}{1 - e^{-a}}\right) h_g \tag{151}$$

$$a = \frac{N_v M_v c_p}{h_g} \tag{152}$$

$$h_g = j c_p G_v / Pr^{2/3} \tag{153}$$

$$K_m = j \left(\frac{G_v}{M_m}\right) Sc^{-2/3} \tag{154}$$

Here, N_v is the molal rate of condensation (mol m^{-2} s^{-1} or mol ft^{-2} h^{-1}), M_v is the molecular weight of the vapor, G_v is the vapor mass velocity, and M_m is the mean molecular weight of noncondensables and vapor.

The Colburn – Edison [125] equation is used to determine the condensation path and the conditions at the next point downstream in the condenser:

$$\frac{dp_v}{dT_v} = \frac{(p_v - p_i)(p - p_v)}{(T_v - T_i)\,\Delta p_{lm}} \left(\frac{e^a - 1}{a}\right) \left(\frac{Pr}{Sc}\right)^{2/3} \tag{155}$$

where

$$\Delta p_{lm} = \frac{(p - p_v) - (p - p_i)}{\ln\left[(p - p_v)/(p - p_i)\right]} \tag{156}$$

and p = total pressure, p_i = interface pressure, and p_v = vapor pressure.

The design procedure for a condenser with noncondensables is as follows:

1) At the vapor inlet, the vapor partial pressures and vapor and coolant temperatures are known. The partial overall coefficient U' can be determined from the condensate, wall, coolant, and fouling coefficients with an equation similar to Equation (7). The heat- and mass-transfer coefficients are determined for the inlet Reynolds number using an appropriate $j - Re$ curve.
2) Assume a value of T_i and find the corresponding value of p_i from the vapor pressure curve.
3) Solve Equation (150). If both sides of Equation (150) balance, then proceed to Step 4, otherwise assume another value of T_i and repeat Steps 2 and 3.
4) For the balanced condition of Step 3 solve Equation (155).
5) Assume a step change in either the vapor temperature or partial pressure, using Equation (155) to determine the step size of the other variable. If the value of Equation (155) is very small, make the assumed step change in the partial pressure; if large, in the vapor temperature.
6) By heat- and mass-balance calculations, the conditions at the next step are determined. Steps 1 to 5 are repeated until the vapor exit conditions are reached: the calculated coolant temperature at the vapor exit should equal the available inlet temperature.
7) Plot $1/(U' \Delta T)$ versus q'', and graphically integrate the curve to determine the required heat-transfer surface area A.

For a condensable binary mixture, the Colburn – Drew [126] equation is

$$U'(T_i - T_c) = h'_g(T_v - T_i) + F'\Delta i \ln\left(\frac{z - y_{Ai}}{z - y_{Av}}\right) \quad (157)$$

where

$F' = j(G_v/M_m)(Sc)^{-2/3}$
$z =$ $\tilde{N}_{Ai}/\tilde{N}_t$ mole fraction of A_i in the total $\tilde{N}_t$ condensing moles
$\Delta i =$ molal heat of condensation
$y =$ mole fraction of component A at $i =$ interface, $v =$ vapor

For multicomponent (3 or more) mixtures, the theoretical equations are unwieldy, and approximation methods such as that by Bell – Ghaly [127] can be used. Here it is assumed that the condensation path follows the boiling point curve.

The design procedure for the Bell – Ghaly method is:

1) Calculate condensing curves as a function of the vapor temperature:
   a) Total condensing stream enthalpy assuming thermodynamic equilibrium between phases
   b) Vapor weight flow rate
   c) Total heat removed from the vapor inlet to a given point Q_T
   d) Coolant temperature
2) For a number of steps along the Q_T curve, calculate the ratio Z of vapor sensible heat removed to the total vapor enthalpy change and plot Z as a function of Q_T.
3) Calculate the condensing film coefficient and the vapor film coefficient as a function of condensate and vapor flows, respectively, and both as functions of the total stream enthalpy Q_T.
4) Calculate U' as a function of Q_T. U' is the partial overall coefficient consisting of the condensate, wall, coolant, and fouling coefficients.
5) Calculate $(1 + ZU'/h_g)/U'(T_v - T_c)$ as a function of Q_T, where T_v and T_c are the local vapor and coolant temperatures, respectively.
6) Calculate A by integrating the function of step 5) numerically or graphically from $Q_T = 0$ to Q_T^* where Q_T^* is the total heat removed in the condenser.

A comparison of the above methods is given in [128] and further information on condenser design and operation in [7], [81–84].

9.1.4. Mean Temperature Difference

The calculation of a single mean temperature difference (usually a log-mean) based on terminal temperatures for condensers is frequently done; however, it is theoretically wrong as the condensing coefficients vary throughout the exchanger. In some cases, the error is not large but the best approach is to calculate the local overall coefficients together with the local temperature differences and integrate the products along the condensation path.

9.1.5. Desuperheating

Vapor may enter the condenser with a large amount of superheat, and, depending upon the local conditions, the tube wall may be dry or may have a condensate layer. If the wall is dry, its temperature must be above the vapor saturation temperature, and the vapor heat-transfer coefficient is that of a gas, and the temperature difference is based on the superheat value. Note that the heat flux will be higher than for the condensing value, as the tube wall temperature is above the saturation temperature. The only exception is where the coolant coefficient is a function of the wall temperature, such as could occur with boiling coolant in the film boiling region. If the wall is below the saturation temperature, a condensate layer is formed whose interface temperature is at the saturation temperature; hence, the temperature difference is based on the saturation temperature. The amount of condensate formed is, however, based on the total heat released which is the latent heat plus the amount of superheat.

9.1.6. Subcooling

All condensate in contact with the condenser tube wall is subcooled because of the temperature gradient across the condensate film. The

amount of subcooling depends on the temperature difference and on whether the film is in laminar or turbulent flow. Often further subcooling is required before the condensate is discharged.

For vertical tube condensers with downward vapor flow, the condensate film below the condensing section will be subcooled and the condensate coefficient is for the laminar region:

$$h\left(\frac{\mu}{k^3\varrho^2 g}\right)_1^{1/3} = 0.78\left[\left(\frac{c_p u}{k}\right)_1\left(\frac{\mu^2}{\varrho^2 g}\right)_1^{1/3}\left(\frac{1}{L}\right)\right]^{1/3}\left(\frac{4\Gamma}{\mu_l}\right)^{1/9} \tag{158}$$

In the turbulent region, $4\Gamma/\mu_l > 2100$, and the following equation should be used:

$$h\left(\frac{\mu}{k^3\varrho^2 g}\right)_1^{1/3} = 5.7\times 10^{-3} Re_l^{0.4} Pr_l^{0.34} \tag{159}$$

where Γ is the condensate mass flow rate per unit perimeter.

Inside the horizontal tubes, the condensate flows in a layer whose thickness, area, and coefficient cannot be predicted with any reasonable accuracy. Subcooling is poor, and this arrangement is not recommended.

Subcooling on the outside of horizontal tube bundles is frequently attempted by creating a dam near the condensate outlet in an effort to create a pool partially submerging the bundle. Although some subcooling is accomplished, it cannot be predicted accurately, as the actual liquid level may be substantially different from the static level because of pressure gradients in the shell. Likewise, the velocity cannot be predicted adequately. A conservative estimate can be made by using a natural convection coefficient with the area calculated on the basis of the static liquid level. Predictability of subcooling is poor, temperature control is almost impossible, and thermal stress problems become important due to differential expansion of the tubes. Separate coolers should be used if subcooling is critical with shellside condensation.

9.2. Vaporizers

9.2.1. Kettle and Internal Reboiler Design

Flow Circulation Mechanism. In a kettle reboiler, the tube bundle is submerged only a few centimeters below the stagnant liquid level. When boiling takes place, the vapor generated within the bundle reduces the local density. Rising bubbles create an upward flow of a vapor–liquid mixture through the bundle and create a froth mound above the bundle. The vapor escapes from the froth and the liquid spills to the bundle sides and returns to the bottom portion through the eccentric annular space between the bundle and the shell. Liquid enters the bundle in the lower half of its periphery. The complex circulation and velocity pattern in the bundle makes meaningful experimental measurements difficult and the effect of circulation on heat transfer has to be deduced from overall performance by means of assumed mathematical models.

The two-phase flow generated within the bundle will affect the heat-transfer rate. In large bundles with small tube pitches, the fraction of vapor can become high enough to vapor blanket (i.e., the mist flow regime) upper bundle portions and reduce performance. Enlarged tube pitches and/or provision of lanes for vapor escape are used in very large bundles.

Boiling Coefficient and Maximum Heat Flux. Since a tube bundle is an assembly of tubes, the basic approach to heat transfer in bundles is to use the single tube pool boiling coefficient modified for the influence of neighboring tubes. Early experiments indicated little difference between single tubes and bundles but later experiments indicated an enhanced performance for bundles.

The bundle average boiling heat-transfer coefficient $h_{\mathrm{tp,\,m}}$ is empirically modeled as

$$h_{\mathrm{tp,m}} = h_{\mathrm{nb1}} F_{\mathrm{B}} F_{\mathrm{m}} + h_{\mathrm{nc}} \tag{160}$$

where h_{nb1} = single-tube nucleate boiling heat-transfer coefficient

$$h_{\mathrm{nb1}} = 0.00417 p_{\mathrm{cr}}^{0.69}\left(q''\right)^{0.7} F_{\mathrm{p}} \tag{161}$$

$$F_{\mathrm{p}} = 1.8\left(\frac{p}{p_{\mathrm{cr}}}\right)^{0.17} + 4\left(\frac{p}{p_{\mathrm{cr}}}\right)^{1.2} + 10\left(\frac{p}{p_{\mathrm{cr}}}\right)^{10} \tag{162}$$

F_{B} = factor for bundle geometry ≈ 1.5 as a conservative value [20], but can range from 1 to 3

F_m = factor for mixtures ($F_m = 1$ for single component mixtures)

$$F_m = \frac{1}{1 + 0.027\,(q'')^{0.1}\,\Delta T_{BR}^{0.7}} \tag{164}$$

form [129]

$$h_{nc} = \text{natural convection heat} - \text{transfer coefficient for a single tube.} \tag{165}$$

In the foregoing equations, p_{cr} is the critical pressure in kPa, q'' is the bundle heat flux in W/m^2, and ΔT_{BR} is the boiling range (= dew point – bubble point temperature) in °C. The last two terms in Equation (162) should be used only when $p/p_{cr} > 0.2$, otherwise they should not be included in the calculation. For mixtures, h_{nb1} in Equation (161) is based on the fluid properties of the light component. The lower limit of F_m is 0.1. Newer developments for F_b involve relating it to the circulation velocities through the bundle but much of this information is based on proprietary data.

The bundle coefficient $h_{tp,m}$ does not show sensitivity to surface conditions; however, finned surfaces do give better performance but mostly due to the increased surface.

The maximum (critical) flux for a bundle is different and lower than the single tube maximum flux. The bundle maximum flux is given as

$$q''_{B,max} = q''_{1,max}\,\Phi_B \tag{166}$$

where

$$q''_{1,max} = 367\,p_{cr}\left(\frac{p}{p_{cr}}\right)^{0.35}\left(1 - \frac{p}{p_{cr}}\right)^{0.4} \tag{167}$$

where p and p_{cr} are in kPa and q'' in W/m^2. Based on some plant experience, Palen and Small [99] proposed a bundle correction model for the vapor blanketing effect. They developed a correction term, Φ_B in Equation (166), which can be simplified to

$$\Phi_B = 2.2\left(\frac{\pi d_B L}{A}\right) = \frac{K p_t}{d_0\,(d_B/p_t)^{1.1}} \tag{168}$$

where

$$K = \begin{cases} 4.12 & \text{for square pitch} \\ 3.56 & \text{for triangular pitch} \end{cases} \tag{169}$$

p_t = tube pitch

and

$$0.1 < \Phi_B < 1 \tag{170}$$

L and A in Equation (168) are the bundle tube length and total outside tube surface area. Equation (168) is reported to be conservative [130].

9.2.2. Horizontal Shellside Thermosiphon Reboiler Design

The horizontal shellside thermosiphon in an X shell arrangement is similar to a kettle except that the circulation through the bundle is controlled by the piping arrangement. In kettles, the circulation pattern and rates are unknown. With the use of baffled shells, E, G, etc., the velocities across the tubes can be increased and the effective depth of a crossflow bundle is increased. With baffled shells, the flow pattern approaches that for vertical in-tube thermosiphons in that the heat-transfer coefficient and pressure drops must be calculated incrementally along the bundle due to the influence of changing vapor quality.

9.2.2.1. Pressure Balance in the Recirculation Loop

A pressure balance is illustrated by Figure 47. The available pressure drop across the exchanger, $p_i - p_e$, is created by the static head (H) differences less other losses in the inlet and outlet piping. Here

$$p_i = p_0 + \varrho_l H_i \frac{g}{g_c} - \Delta p_l - \Delta p_m \tag{171}$$

and

$$p_e = p_0 + \varrho_{tp} H_e \frac{g}{g_c} + \Delta p_{f,tp} + \Delta p_{m,tp} \tag{172}$$

where Δp_l and Δp_m are the pressure drops due to the frictional and momentum change for liquid entering the exchanger, and $\Delta p_{f,tp}$ and $\Delta p_{m,tp}$ are the pressure drops caused by frictional and momentum change for the two-phase mixture leaving the exchanger.

Figure 47. Horizontal thermosiphon reboiler installation with various pressure and static head terms

9.2.2.2. Shellside Heat Transfer and Pressure Drop

There is little published heat-transfer data for two-phase shellside boiling; a summary is given in [77]. The basic approach is similar to two-phase flow in tubes. The various bypass and leakage streams that exist for shellside flow and their effect for single-phase and two-phase flows complicate the analysis. The single-phase leakage effects are known but the bypass and leakages may be different for two-phase flows. The shellside heat transfer can be determined as:

$$\frac{h_{\mathrm{tp}}}{h_{\mathrm{lo}}} = \left(\frac{\Delta p_{\mathrm{f,tp}}}{\Delta p_{\mathrm{l}}}\right)^n \tag{173}$$

where n seems to range from 0.4 to 0.5 and an average of 0.45 can be used. The heat-transfer coefficient h_{lo} and pressure drop Δp_{l} are calculated according to methods given earlier (Chapter 8) where allowances are made for flow bypass and leakage, and in this manner some correction is also made for the two-phase flow leakages.

9.2.2.3. Design Methods and Special Considerations

Horizontal shell thermosiphons have used many types of shells, X, E, G, etc., and their selection is influenced by heating medium flows, temperatures, etc. as well as the physical restraints of available heights and ground area. This selection process is beyond the present scope and a simple E shell is used for basic discussion.

Tube diameter and length are mostly based on the heating medium requirements. Tube pitch ratio is usually 1.25 – 1.33 and a square arrangement, either staggered or inline, is used to allow for cleaning. Segmental baffles with somewhat larger baffle cuts (ca. 35 %) are used and placed on proper spacings to avoid vibration problems. The baffle cuts may be horizontal or vertical. Horizontal cuts promote better mixing but have higher pressure drops, while vertical cuts may have phase separation and possible different tube wall temperatures in each phase zone.

The vaporization fraction should be kept low to achieve higher circulation rates, lower fouling and higher heat-transfer coefficients. The available head will limit the allowable pressure drop and circulation. The discharge piping for the vapor – liquid mixture must also be sized to keep the frictional pressure drop low yet keep the mixture out of the slugging flow regime for the expected range of process operations. The shellside flow patterns and flow pattern maps are shown in Figures 39 and 42.

The heat-transfer and pressure drop calculations are made on an incremental basis by calculating a preheating zone and then by selected increments of vaporization for the boiling zone. Since the design process starts with an assumed arrangement and is then modified by iteration, the use of computers is essential although hand calculations are possible but tedious.

The designer should at all times be aware of the limitations of these methods and flow pattern maps.

9.2.3. Vertical Thermosiphon Reboiler Design

The hydrostatic head on the liquid entering the tubes results in a subcooling with respect to the local pressure, thus there is a liquid preheating zone required to bring the liquid to the boiling point as it rises through the tube. The boiling zones can consist of several types: subcooled

boiling, nucleate boiling modified by a superimposed two-phase convective flow, mist flow, or film boiling also modified by the liquid core velocity. Heat-transfer and pressure-drop relations for each of these zones are different, hence each zone is calculated separately. For the two-phase flow zones, further subdivision is necessary to account for the changing ratio of liquid to vapor. Various zones and the effects on wall temperature and heat transfer are shown in Figure 44.

9.2.3.1. Pressure Balance in the Recirculation Loop

Vertical thermosiphons require the simultaneous solution of flow and heat-transfer rates in the complete recirculation system. As shown in Figure 44, the driving force for the circulation is the static head of liquid in the column base or reservoir which must equal the various losses. That is

$$\Delta p_{\mathrm{T}} = \Delta p_{\mathrm{i}} + \Delta p_{\mathrm{t}} + \Delta p_{\mathrm{e}} \tag{174}$$

where the total pressure drop Δp_{T} is the available head in the reservoir. The inlet piping and header losses, Δp_{i}, are easily calculated for the liquid flow. The pressure losses in the tubes, Δp_{t}, due to the changing ratio of the two phases, is a difficult calculation. It requires an incremental determination along the tube of the flow pattern and the associated hydrostatic, acceleration, and frictional losses. The exit head and piping losses, Δp_{e}, must be kept at $< 30\,\%$ of Δp_{T} to avoid stability problems and can only be approximated due to lack of data.

In the following discussion, the heat-transfer and pressure-drop methods for each flow regime are considered together.

9.2.3.2. Flow Regimes and Heat Transfer

Non-Boiling Zone. The liquid entering the tube is at a higher pressure than its saturation pressure leaving the tubes due to the static head; hence, sensible heat is required to bring the liquid to its local boiling point plus any superheat to activate the bubble nuclei. The liquid zone heat-transfer coefficients are calculated as follows: For the laminar flow where $L/d_{\mathrm{i}} > 50$ and $Re < 2300$, the empirical modification of the laminar flow equation is [60]:

$$Nu_{\mathrm{l}} = 0.17 Re_{\mathrm{l}}^{0.33} Pr_{\mathrm{l}}^{0.43} \left(\frac{Pr_{\mathrm{l}}}{Pr_{\mathrm{w}}}\right)^{0.25} Gr_{\mathrm{l}}^{0.1} \tag{175}$$

where

$$Gr_{\mathrm{l}} = \frac{d_{\mathrm{i}}^3 \varrho_{\mathrm{l}}^2 g \beta (\mathrm{T_w} - T_{\mathrm{l}})}{\mu_{\mathrm{l}}^2} \tag{176}$$

Here the natural convection effect in laminar flow is accounted for by the Grashof number term ($Gr_{\mathrm{l}}^{0.1}$); β is the coefficient of thermal expansion in 1/°C (or 1/°F).

For the transition and turbulent flow regions, $Re > 2300$, and the Gnielinski correlation, given in Table 10, should be used.

The pressure drop for the preheat zone is

$$\Delta p = \left[\frac{4 f G^2}{2 g_{\mathrm{c}} d_{\mathrm{i}} \varrho_{\mathrm{l}}} + \varrho_{\mathrm{l}}\right] L_{\mathrm{ph}} + 0.5 \frac{G^2}{2 g_{\mathrm{c}} \varrho_{\mathrm{l}}} \tag{177}$$

where L_{ph} is the preheat zone length. The last term of Equation (177) represents the pressure drop due to acceleration.

Subcooled Boiling Zone. A subcooled boiling takes place when the local tube wall temperature is sufficiently high to initiate bubble formation on the wall nuclei, and when the local bulk liquid temperature is below the local boiling point. The formation of bubbles at the nuclei and the bubble collapse due to the subcooled state of the bulk of the liquid causes an increase in heat transfer but the rapid collapse of the bubble has very little effect on acceleration of the fluid or its density, thus liquid properties are used.

The agitation due to bubble formation and collapse increases the heat flux as an additional heat flux q''_{nb} to the heat flux q''_{l} due to the convective flow of the fluid. Their sum is the total heat flux q''. In terms of the boiling coefficient, this is

$$h_{\mathrm{tp}} = h_{\mathrm{nb}} \left(\frac{T_{\mathrm{w}} - T_{\mathrm{sat}}}{T_{\mathrm{w}} - T_{\mathrm{l}}}\right) + h_{\mathrm{l}} \tag{178}$$

where h_{l} is the same as the liquid single-phase coefficient in the preheat zone, Equation (175) or the Gnielinski correlation (see Table 10), and h_{nb} is determined from some suitable predictive equation for nucleate boiling. Usually h_{nb} is based on equations for single tube nucleate

boiling in pools (see subsection on the Boiling Zone below).

The pressure drop in this zone is calculated as in the preheat zone since it is assumed that the rapid collapse of bubbles results in a negligible vapor fraction and neglible acceleration.

Boiling Zone. Once the bulk temperature reaches the local saturation temperature, the bubbles accumulate and the vapor fraction increases; a variety of two-phase flow patterns are found such as bubble, slug, or annular. The boiling heat-transfer zone extends to the location where the mist zone begins. As a result of the changing vapor fraction, the local heat-transfer rates vary and it is necessary to calculate the local heat fluxes for incremental steps in vapor fraction or in incremental lengths of the tube.

The boiling heat-transfer coefficient h_{tp} is again a function of the convective and nucleate boiling coefficients (see Eq. (124)).

The saturated flow boiling heat-transfer coefficient can not be predicted with a high degree of accuracy as its value is dependent not only on the physical properties and heat flux, but also on the surface characteristics, flow regimes and flow rates, and on mass transfer in both phases. The nucleating characteristics of surfaces are presently impossible to specify and, furthermore, they change due to deposits or corrosion.

The maximum heat flux has been empirically correlated and given by Equation (129) or (136).

Mist Zone. The mist zone is not often encountered in vertical tube thermosiphons as the fraction vaporized per pass is normally too small.

The small volume of liquid in mist flow is entrained as droplets and the tube wall is essentially dry thus the coefficient approaches that for gas flow. In this regime, sensible heat is transferred to the gas which in turn transfers some of the heat to the droplets until they are completely evaporated after which only sensible heat transfer takes place. The main problem is the determination of the vapor temperature, and hence the temperature difference. The two extreme conditions are: (1) no heat is transferred to the droplets so that the vapor temperature rises rapidly; and (2) heat is rapidly transferred to the droplets until they disappear and the vapor is at the saturation temperature during this evaporation phase. Condition 1 is approached at low pressures and velocities, and condition 2 at high pressures and velocities. The actual case is somewhere inbetween. An intermediate result can be obtained by assuming half or more of the heat is transferred to the droplets and the remaining heat raises the vapor temperature. The LMTD and heat flux can then be calculated.

The mist region can be determined from the following equation which is based on the Fair map [131]

$$G_{\mathrm{m}} = cX_{\mathrm{tt}} \tag{179}$$

where G_{m} is the maximum mass velocity before mist flow begins and $c = 2.44 \times 10^3\ \mathrm{kg\,m^{-2}\,s^{-1}}$ or $1.8 \times 10^6\ \mathrm{lbm\ ft^{-2}\,h^{-1}}$.

Film Boiling. This type of boiling should be avoided due to control problems, possible fouling, and lack of data on pressure drop calculations. For unavoidable high temperature differences, the film boiling heat-transfer coefficient can be calculated by the Glickstein and Whiteside correlation [132]:

$$\frac{hd_{\mathrm{i}}}{k_{\mathrm{v}}} = 0.106 Re_{\mathrm{v}}^{0.64} Pr_{\mathrm{v}}^{0.4} \left(\frac{\varrho_{\mathrm{m}}}{\varrho_{\mathrm{v}}}\right)^{0.5} \tag{180}$$

where the bulk mean density on a no-slip basis is

$$\varrho_{\mathrm{m}} = \frac{\varrho_{\mathrm{l}}}{1 + x\left(\frac{\varrho_{\mathrm{l}}}{\varrho_{\mathrm{v}}} - 1\right)} \tag{181}$$

In film boiling inside a tube, a core of liquid is surrounded by an annular layer of a low viscosity gas, thus the frictional pressure drop will be low. The major losses are due to hydrostatic head and momentum losses. Since the liquid core velocities can easily increase by a factor of 2 or more, the losses in external piping due to the higher circulation also become significant.

9.2.3.3. Approximate Design Methods

The maximum heat flux in thermosiphons with essentially no inlet and exit nozzle and piping losses is limited by a surging of flow through the exchanger. This surging instability is a function of the boiling fluid and the operating conditions, and is dependent upon the hydraulic resistances in the piping circuit. It is very sensitive

to pressure drop in the exit vapor-mixture lines, which should be kept $< 30\,\%$ of the total available head. It is strongly recommended that the cross-sectional flow area of the exit pipe be equal to the total cross-sectional area of the tubes. Increasing the flow resistance in the inlet pipe, however, has a stabilizing effect, thus the use of a valve or orifice should be anticipated. The inlet line usually has a cross-sectional area of $20-50\,\%$ of the total tube cross-sectional area.

If the available temperature difference is sufficient to reach $q''_{\mathrm{B,\,max}}$ (generally $> 45\,^{\circ}\mathrm{C}$ or $80\,^{\circ}\mathrm{F}$), then the thermosiphon design is a selected fraction ($\lesssim 0.7$) of $q''_{\mathrm{B,\,max}}$, where the fraction is based on the effect of potential process upsets. When the maximum available temperature difference is insufficient to reach $q''_{\mathrm{B,\,max}}$, the tube must be divided into a nonboiling preheat zone and a boiling zone for a preliminary and quick calculation. An average vapor fraction is used to calculate the boiling zone. The tube inlet velocity is assumed to be $0.3-1$ m/s ($1-3$ ft/s), and the heat transfer and pressure drops are calculated. Several trials may be needed to reach a solution where the pressure drop equals the available pressure head.

A better calculation can be made by dividing the tube into a number of sections and calculating the heat transfer and pressure drop by the method above. Such calculations are incorporated into computer programs due to the complexity and number of calculations involved. Although the computer results may give a better answer than the approximation methods, the predictability of boiling heat transfer is poor and substantial errors ($> 30\,\%$) are still possible.

9.2.4. Special Design Considerations

Circulation through the thermosiphon is an important and necessary characteristic of the vaporizer. Many of the piping features and operating limits have already been discussed; however, those as well as methods and experimental tests pertain to narrow boiling range liquids. Wide boiling range mixtures, especially those where the maximum boiling point exceeds the available heating medium temperature, may cease to circulate unless the liquid level is sufficiently high to provide a complete liquid circuit, or if vapor sparging beneath the lower tubesheet is used to initiate circulation.

Thermosiphons operate best in the pressure range of moderate vacuum where the boiling point elevation due to the static head is not too large to about half the critical pressure. Beyond these limites the preheating zone becomes too large and the available driving force for circulation is insufficient.

As in all vaporizers, the maximum and minimum temperature differences need to be determined for clean and fouled conditions and for the range of process flows and pressures in order to acertain that the vaporization is controllable; e.g., in steam heated systems is it possible for condensate to be removed and for the inerts to be vented?

9.2.5. Mean Temperature Difference

For boiling outside of tubes, the determination of a mean temperature difference is an arbitrary choice based on the amount of subcooling in the feed, the difference between the boiling points of entering and leaving liquid, and to some extent, the geometry of the reboiler. The problem is the degree of mixing that occurs in the shell which depends on the circulation rate. As described in [130], the bulk temperature within the tube bundle varies with the length and the effective ΔT differs substantially from the ΔT based on exit temperatures; thus, depending upon the idealizations, several methods of calculating the mean temperature difference can be used. Some of the choices are:

1) For a pure component or a narrow boiling range mixture and a constant temperature heating medium, the difference between the condensing and boiling temperatures is used. If the heating medium is transferring sensible heat, a logarithmic mean of the vapor saturation temperature and the heating medium terminal temperatures is used.
2) For a wide boiling range mixture or where the sensible heat load is a substantial fraction of the total heat load, a counterflow logarithmic mean temperature difference (LMTD) gives optimistic results [130] and a LMTD based on the exit vapor temperature is recommended.

3) When the effect of static head on the boiling point is significant, e.g., in large bundles and/or vacuum service, the boiling temperature should be based on the mean pressure in the bundle including the imposed static head.
4) When a horizontal thermosiphon reboiler is used, a counterflow LMTD is very optimistic and use of a parallel flow LMTD is suggested.

Experimentally measured boiling coefficients and any resulting correlations are dependent on the temperature differences used to calculate these coefficients from the original test data. The same MTD should be used in the design of reboilers when using these data or correlations. However, the generalized correlations given above have such a spread of data that the temperature difference determination is a minor factor in the data spread and the MTD suggestions in the above paragraph should be followed.

9.2.6. Common Problems with Reboilers in Practical Applications

Dryout. If the surfaces are not wetted, it is obvious that no boiling can take place. A nonwetted condition or its equivalent can occur due to: (1) insufficient liquid level; (2) too high a vaporization, i.e., $> 50\,\%$ by weight of vapor where a mist flow regime occurs and the surface dries; 3) too high a temperature difference so that film boiling occurs; and 4) an equivalent effect occurs when some of the low boiler is stripped from the feed, thus increasing the boiling point of the remaining solution so that the temperature difference required for boiling decreases to zero. This phenomenon occurs when the natural circulation path from the reboiler to the distillation column is incomplete, e.g., in vertical tube thermosiphons, the liquid level is at the upper tubesheet but the connecting vapor pipe is above the tubesheet. As a result, the concentrated solution in the thermosiphon can not circulate and mix with the feed solution in the column. The remedy is to increase the liquid level to the midpoint of the horizontal vapor pipe or to sparge a vapor beneath the lowest tubesheet to promote circulation.

Overdesign is very common due to conservative design methods and to fouling allowances. Control of boiling rate then becomes difficult since the required steam pressure may be too low to permit discharging condensate to the condensate return system. The condensate level can build up in the exchanger to blanket the excess surface and may block the vents so that venting the inerts may cease. When the control valves increase the steam pressure sufficiently to discharge the condensate and the inert gases, the increased surface and thus boil-up will result in a cycling effect of the boil-up rate.

Fouling in evaporators can occur by decomposition reactions of the process fluids, corrosion of tube surfaces, or deposition of solids in the feed. Prediction of the fouling rates is impossible due to lack of knowledge of this process, thus a fouling coefficient is just an arbitrarily assumed value. Since the boiling coefficients are very sensitive to its film temperature difference, the effect of even a small temperature drop across the fouling layer has a greatly magnified effect on the heat flux. Being overly conservative in the assumed fouling coefficient can increase the problem of controlling the boil-up as explained for oversized surfacing.

Instability and Its Remedies. Instability results from a feedback between the rate of boiling and the rate of circulation. The phenomenon is mostly encountered in the thermosiphon types of reboilers and is characterized as a surging or oscillating flow. Several theoretical analyses have been made [133], [134], and it usually occurs under certain conditions of boil-up and circulation. Surging is easily suppressed by adding a resistance, a valve or orifice, in the circulation line to the evaporator. Such a resistance has the effect of having a higher resistance in back flow than in forward flow and thus has a stabilizing effect. A similar effect may occur in kettle reboilers where a sudden evolution of vapor forces out the liquid which then later rushes back in when the vapor escapes and the cycle repeats. The only recourse here is to try changing the liquid level otherwise tubes would be removed to allow for easier escape of the vapor.

Vapor Separation for the thermosiphon type of reboilers takes place in the reservoir vessel or more commonly in the base of the distillation column. Here some space is allowed

between the inlet nozzle and the bottom plate to allow for vapor separation. The column vapor velocity will then control the amount of entrainment.

Kettle reboilers with a bundle diameter 60 % of the shell diameter provides a minimum space for vapor separation. Some small amount of entrainment is expected. If a dry vapor is required, additional separating devices should be employed and if the boiling liquid has any tendency to foam or froth, special separators will be required as the normal designed (40 % of shell diameter) vapor space is inadequate. Increasing the number of vapor nozzles in order to reduce the horizontal flow velocities also helps in reducing the entrainment.

For the internal reboiler, considerable space is needed between the liquid level and bottom plate as the vapor – liquid mixture can shoot up several feet above the tube bundle. The height of throw will be a function of bundle diameter and vapor mass velocity.

Others. Location of a fresh feed line to a circulating type reboiler can influence its operation. In refrigeration systems, a mixture of vapor and liquid from the expansion valve is fed to the bottom of the horizontal tube bundle. Feeding close to the low temperature difference end of the tube bundle can improve the circulation and heat transfer at that end. For wide boiling range mixture with a low concentration of low boiler, the circulation may stop if the stripped low boiler can escape without promoting circulation. Here sparging of a vapor beneath the lower tubesheet will promote and maintain a circulation.

Operating across the maximum flux point should not be attempted as crossing this point reverses the effect of control instruments, e.g., an increase in steam pressure will result in less boil-up when in the film boiling zone.

10. Flow-Induced Vibrations

There are two basic types of flow-induced vibrations in heat exchangers: (a) tube vibration, and (b) acoustic vibration (for gas flows only) that can exceed 160 dB. While the reported frequency of such problems with heat exchangers is < 1 % of the installed exchangers, the costs involved to correct such failures justify checking the thermally designed exchanger for potential vibration. The methods to be described below are based on idealized tube bundles and single-phase flows (little information exists for two-phase flow); they only approximate the conditions existing within an exchanger. Better predictions can be made using computer programs that calculate the flow distribution within the shell, but even here some uncertainty exists due to the lack of knowledge of tube stresses formed during fabrication and during operation.

Tube vibration occurs when an exciting forcing frequency is within $\pm$ 20 % of the tube natural vibration frequency and coupling takes place. Tubes may then fail or damage as a result of: (1) Collision with adjacent tubes or shell walls due to a large amplitude of vibration. The collision produces a diamond-shaped wear pattern at the midspans of the tubes and could eventually rupture the tubes. (2) Fretting wear. Because of the clearance between the baffle hole and the tube, the tubes are free to move. Hence, the vibrating tubes can be cut by the baffles if the tubes are softer than the baffle, or the baffle ligament is cut. (3) Cutting of the tubes at the tubesheet due to maximum stress as a result of a lateral deflection. (4) Fatigue. Sustained tube vibration for a long period can produce failure due to fatigue of either the tubes or of the tube-to-tubesheet joints; any tube material defect can propagate and result in tube failure. Oxidation of the tube material and erosion and corrosion can also accelerate fatigue failures.

Acoustic vibration occurs for gas flows when the forcing frequency (flow or heat transfer induced) matches the natural frequency of the shellside gas column. The resulting acoustic resonance is intense and low frequency, and causes severe vibration and fatigue damage to the shell, connecting pipes, and floor. If the frequency of the standing wave coincides with the tube natural frequency, tube failure may occur.

A procedure follows which outlines whether or not there will be a flow-induced vibration problem, and some methods are described to prevent or reduce tube vibration and acoustic vibration. Further details and correlations are given in [135].

10.1. Vibration Analysis

For a thermally designed exchanger, the following is a procedure to determine if there is a vibration problem [135]:

1) Compute the tube natural frequency for straight plain or finned tubes and U-tube bundles [2], [25], [135], [136]. The tube natural frequency should be calculated for tubes in the end regions and window zone, and corrected for axial loads if any.
2) Calculate the crossflow (gap) velocity in the end regions and central region of the tube bundle, and compute the axial velocity in the window zone.
3) Determine the vortex shedding frequency and turbulent buffeting frequency in the end regions and window zone of the tube bundle [137–140]. If either of these frequencies is within 20 % of the tube natural frequency, then resonance is likely to occur. In that case, compute the vibration amplitude, which should be limited to 2 % of the tube outside diameter, *OD,* to avoid damage to the tubes.
4) Estimate the critical velocity for fluid-elastic whirling in the end regions and in the central region of the bundle [141–143]. Compare these velocities with the crossflow velocities computed in step 2 above. If the crossflow velocity is higher than the estimated critical velocity, tube vibration will occur due to fluid elastic whirling. It is currently believed that fluid-elastic whirling, and not vortex shedding or turbulent buffeting, is mostly responsible for tube vibration.
5) Compute the acoustic frequency on the shell side. Acoustic vibration is likely to occur if it is within 20 % of the vortex shedding frequency, turbulent buffeting frequency, or tube natural frequency [135], [144], [145]. Acoustic vibrations can also be generated by the heat-transfer process itself [146–148].

If the above analysis indicates that tube vibration or acoustic vibration is possible, or remedied, the shellside design must be modified as discussed in the next section.

10.2. Design Guidelines for Vibration Prevention

Vibration problems are best prevented rather than corrected. After the heat exchanger has been designed for thermal and hydraulic performance, it should be checked for flow-induced vibrations. Once the sources and frequency of vibration have been identified, either the lowest natural frequency of the tubes should be increased sufficiently so that it is higher than the highest excitation mechanism or the sources of vibration mechanisms should be eliminated or minimized. For acoustic vibrations, detuning baffles can be installed. Further details and discussion are presented in [25], [135].

10.2.1. Tube Vibration

Tube vibration can be reduced within limits by either increasing the tube natural frequency, or reducing or eliminating the crossflow velocity component. There are, however, two designs that have no tube vibration problems: (1) The no-tube-in-window design (Fig. 26), where tubes in the window zone are eliminated and sufficient intermediate support plates are used to prevent tube vibration. (2) The rod or honeycomb type of tube supports (Fig. 27), which stiffen the tube bundle and prevent tube vibration, but here the shell fluid flows parallel to the tubes.

The tube natural frequencies can be increased by reducing the baffle spacing or by adding intermediate partial support plates. Tests have shown that the critical tube rows are those just beyond the baffle tips and that partial support plates (strip baffles) as shown in Figure 48 are effective [149]. Field fixes are lacing the tubes if the tube layout permits it or removing some tubes.

Figure 48. Strip baffles to protect tubes in the window zone a) Segmental baffle; b) Strip baffle

The crossflow velocity, which is the source of the excitation forces, can be reduced by increasing baffle spacing, increasing tube pitch, using multiple segmental baffles, or changing to X or J shells.

10.2.2. Acoustic Vibration

The acoustic vibration can be eliminated by disturbing or destroying the standing wave or changing the character of vortex shedding by one of the following methods:

1) Addition of a detuning baffle close to the pressure node. The detuning baffle should not span the whole tube field in order to minimize the flow disturbance on the shell side.
2) The damping of standing waves could also be accomplished by the use of a porous baffle in place of the solid detuning baffle. While there are a number of detuning baffles required for a tube bundle with the inline arrangement, only one porous baffle is required to detune multiple resonant acoustic modes [150].
3) Selective removal of a few tubes at the displacement antinode of the standing wave will eliminate the vortex shedding and hence the coupling between acoustic frequency and vortex shedding frequency, thus avoiding the acoustic resonance [151].
4) Installation of an acoustic damper such as a tuned Helmholtz cavity resonator on the outside of the shell or acoustic damping material in the exchanger side walls.

None of the above methods of avoiding tube or acoustic vibrations is an ideal solution to the problem, and each will have some disadvantages that apply to the specific exchanger.

Developments of flow-induced vibrations in heat exchangers are dealt with in [152–155].

11. Flow Maldistribution

Heat exchangers are designed on the premise that the flow through the exchanger is steady and uniformly distributed, conditions which almost never exist in industrial heat exchangers.

Flow maldistributions are caused by:

1) Mechanical design, basic geometry and tolerances
2) Self-induced as a result of the heat-transfer process
3) Mixed-phase flows, e.g., gas – liquid
4) Fouling

11.1. Causes of Flow Maldistribution

11.1.1. Mechanical Design, Basic Geometry, and Tolerances

In shell-and-tube exchangers, the design of the entry region (heads, nozzles, manifolds), due to space limitations and cost, results in some flow maldistribution into the tube bundle. Some measurements on large exchangers are reported in [156]. The head design limits the ability to place the tubes close to the shell, thus resulting in a bypass clearance between the tube bundle and shell. This space may or may not be partially closed by the use of side strip baffles. To assemble the exchanger, some clearances are required between the tubes and baffles, and between the baffle and shell and the clearances along with their mechanical tolerances result in leakage areas.

In plate heat exchangers, the manifolds are used to distribute the fluids into and out of the exchanger. Because of the different pressure drops associated with different amounts of fluid flowing axially in the manifolds, flow maldistribution occurs; it becomes more severe as the number of plates is increased per pass.

In compact plate – fin and regenerative surfaces, the flow passages have a small hydraulic diameter. Manufacturing tolerances become very critical in order to maintain uniform flow through highly compact flow passages in laminar flow.

11.1.2. Self-Induced Maldistribution

Flow uniformity can become upset due to heat transfer, which causes viscosity changes, two-phase flows, or density differences. These maldistributions can be either steady state maldistributions or a transient or oscillating flow.

In laminar liquid flow, there can be a large increase in viscosity through the exchanger, such

as cooling of a viscous fluid. As a result, some of the tubes can "freeze" with the high viscosity fluid while other tubes flow with a lower viscosity. This condition can be predicted and avoided [157], [158]. Density changes can also result in maldistribution. Thermoacoustic oscillations occur under certain combinations of flow, geometry, and heat transfer to gases. These vibrations can be sufficiently intense to affect heat transfer, be unpleasantly loud, and can even damage the equipment. Gas flows across tube banks can also result in acoustic and tube vibration problems.

11.1.3. Mixed-Phase Flow

Uniform distribution of a two-phase mixture into a tube bundle (so that each tube gets the same quantity and quality of fluid) is almost impossible. For shellside flow, the possibility of separation due to gravity must be considered especially for horizontal flow. In boiling systems, there are two types of flow maldistributions: (1) Different flow rates can exist between parallel tubes having the same terminal pressures due to the variation of vapor quality in the tubes, sometimes known as the Ledinegg instability; (2) The second type is the more complex oscillating flow and pressure drop known as a density-wave instability (also described as a "steam" or "water hammer").

In condensers, the density-wave instability can also occur under the right conditions. Flow maldistribution can also occur due to the possible accumulation of noncondensable gases in the colder regions of the condenser.

11.1.4. Fouling

Any nonuniformity of fouling within the exchanger affects the local flow rates and will in turn have the feedback effect of increasing the fouling rates.

11.2. Consequences of Maldistribution

11.2.1. Shell-and-Tube Exchangers

Maldistribution in exchangers affects their thermal performance and may damage the exchanger. Thermal performance is most seriously affected when the fluid bypasses the heat-transfer surfaces. Normally flow nonuniformity is not very large and has a small effect on the thermal performance unless the required NTU is > 5 or the secondary fluid conditions result in a temperature pinch. Damage can occur due to the kinetic energy in the liquid slugs of the density-wave oscillation, the vibrations induced by the acoustic phenomenon, or thermal stresses due to large temperature differences in the tube walls in various sections of the bundle, e.g., a horizontal condenser with the lower tubes in a cold condensate pool and the upper tubes in a hot vapor. A fluctuating wall temperature can result in fluctuating stress and metal fatigue, e.g., when hot surface is quenched by waves of fluid.

Systems having radiant, electrical, or nuclear sources of energy are very susceptible to damage due to maldistribution. Here the rate of heat flow is unaffected by the flow or temperature of the fluid. Hence, fluid and/or tube wall temperatures can readily exceed safe limits.

Any flow maldistribution also results in a temperature pattern maldistribution depending on the flow and temperatures of the secondary fluid. Studies indicate that it is this change in the temperature difference that has the greatest effect on the thermal performance rather than variations in the heat-transfer coefficient. In analyzing data taken on exchangers with some maldistribution for comparison with literature correlations, it is very important to correct the temperature difference calculated from the measured terminal temperatures for the effect of internal maldistribution.

Both fluids in an exchanger are subject to maldistribution and the combined effect can result in an excessive thermal stress.

Sixteen papers on the subject of flow maldistribution are contained in [159]. More detailed information into the rather extensive literature on this subject, especially that dealing with instabilities, is to be found in [160] which contains 102 references.

11.2.2. Other Exchangers

Manifold-induced flow maldistribution can be significant and can have a significant influence

on reduction of heat transfer. For further information, refer to [161–165]. Guidelines for the design of manifolds are summarized in [27].

Gross maldistribution at the core inlet is a nonuniformity on a macroscopic level. It is a result of either inlet header shape, upstream flow conditions, or a gross blockage in the heat exchanger core (plugged tubes or flow passages); this may be due to brazing, soldering, or other manufacturing considerations. This nonuniformity causes a significant increase in pressure drop with some reduction in heat-transfer rate [27].

In highly compact heat exchangers, the small flow passages are not identical as a result of manufacturing tolerances. Differently sized and shaped passages exhibit different flow resistances resulting in nonuniform flow distribution, even when the flow approaching the core face is uniform. Thus, this passage-to-passage maldistribution occurs within a core on a microscopic level. It reduces heat transfer significantly, and also reduces the pressure drop slightly [27].

11.3. Recommendations for Shell-and-Tube Exchangers

Normally the maldistribution due to entrance flow does not have a large (usually $< 10\,\%$) effect on thermal performance; however, an impingement baffle is recommended to improve distribution. The internal bypassing and leakages are to some extent allowed for in the stream analysis methods or the Delaware method of calculation. However, an additional allowance should be made for the bypass effect on temperature differences using either the Fisher and Parker curves [107] or the semiempirical methods in some proprietary computer programs.

Any laminar flow exchanger having a large viscosity increase should be checked for maldistribution [157], [158].

The instabilities in vaporizers can be controlled by restricting the liquid circulation. In condensers, most problems are resolved through good venting and good condensate drainage.

The acoustical vibration problems are usually cured by proper placement of detuning baffles.

12. Fouling

Fouling occurs over a period of time with the deposition of solids on heat-transfer surfaces. This solid layer adds an additional resistance to heat flow and can also increase the resistance to fluid flow. The accumulation of this layer can be classified as:

Precipitation Fouling. This is the deposition of dissolved substances on the surface when the surface concentration exceeds the solubility limit. If the deposited layer is hard and tenacious, it is often referred to as "scaling". If it is porous and mushy, it is called "sludge".

Particulate Fouling. Here finely divided solid particles settle on the surface as a result of gravity or other attractive forces. If settling occurs due to gravity, it is referred to as *sedimentation fouling.*

Chemical Reaction Fouling. In this mechanism, solids are formed as a result of reactions, such as coking or polymerization, at the heat-transfer surface in which the surface material does not participate in the chemical reaction.

Corrosion Fouling. The heat-transfer surface reacts with the fluids and the resulting corrosion products form an insulating layer.

Biological Fouling. Various organisms (micro and/or macro) attach themselves to the surface and grow in place.

Solidification Fouling. This results from the freezing of the fluid or a component of the fluid on a subcooled surface.

Very often several of the above classes of fouling occur simultaneously and frequently in a synergistic manner.

Fouling is very costly since it (1) increases capital costs due to the need to oversurface the heat exchanger and for cleaning; (2) increases maintenance costs resulting from cleaning, chemical additives, or troubleshooting; (3) results in loss of production due to shutdown or reduced capacity; and (4) increases energy losses due to reduced heat transfer, increased pressure drop, and dumping of dirty gas streams it present. Fouling promotes corrosion, plugging, and failure of uncleaned exchangers. Gas-side fouling can also be a potential fire hazard.

Fouling significantly reduces heat transfer with a relatively small increase in pressure drop in systems with liquid flows and high heat-transfer coefficients. For systems having low heat-

Table 22. Influence of operating variables on liquid-side fouling

Variables	Precipitation	Solidificiation	Particulate	Chemical reaction	Corrosion	Biological
Temperature	↑↓	↓	↑↓–	↑↓	↑↓	↑↓–
Velocity	↓–	↑↓	↓	↓	↑↓–	↑↓
Supersaturation level	↑	↑				
pH	↑		↑↓		↑↓	↑↓
Impurities		↓				
Concentration	↑	↑	↑			
Surface roughness	↑	↑	↑–		↑–	↑
Pressure	–	–		↑	↑	↑↓
Oxygen	–	–		↑	↑	↑↓

transfer coefficients such as with gases, fouling increases the pressure drop significantly with some reduction in the heat transfer [27].

The rate of fouling is a complex function of time and can be linear, falling rate, or asymptotic depending on the mechanism of formation and solid removal, if any, by an erosion or spalling mechanism. Often there may be an induction period before fouling begins. Many factors affect fouling rates such as temperature, fluid velocity, concentration, surface material and its condition, in addition to the mechanisms influencing several classes of fouling involved. The qualitative effect of some of the operating variables on various fouling mechanisms is shown in Table 22 for liquid-side fouling and in Table 23 for gas-side fouling. In these tables, when the value of a variable is increased, it increases (arrow going up), decreases (arrow going down), or has no effect (a dash) on the specific fouling mechanism listed. Blank blocks indicate that no influence of these variables has been investigated and reported in the literature.

Table 23. Influence of operating variables on gas-side fouling

Variables	Solidification	Particulate	Chemical reaction	Corrosion
Temperature	↓	↓↑	↑	↑↓–
Velocity	↓	↓↑–	↑↓–	↑–
Impurities	↓			
Concentration	↑	↑		↑
Fuel – air ratio		↑	↑	
Surface roughness		↑–		↑–
Oxygen	–	–	↑	
Sulfur			↑	↑

Some progress in understanding the nature of fouling has taken place during the past twenty years as documented in [166–170], but except for cooling waters, very little has been quantitatively correlated for the design of heat exchangers. Much of the fouling research needs to be confirmed by plant operation before being acceptable for design use. In addition, these prediction methods require much more information concerning the process and the exchanger environment than is usually available to the designer.

Present practice is to arbitrarily select a fouling coefficient (or its inverse, the fouling resistance) based on TEMA tables, or if available, based on plant experience for similar process fluids. This is equivalent to specifying an unknown variable coefficient as a fixed constant in Equation (7). Ideally the fouling coefficient selected should involve economic factors such as the cost of excess (over the clean theoretical) area, cost of cleaning, lost production due to cleaning, etc. It is not unusual to encounter designs where the assumed fouling resistance is greater than the process fluid resistance that was determined by detailed and lengthy calculations.

The TEMA tables were developed in the early 1940s by a consensus of opinions and not on any documented test data. The original tables have been slightly revised and extended and owe their continued existance to the fact that exchangers designed and based on these values may not represent the actual fouling but may cover other errors, such as the effect of maldistribution on the effective temperature difference that were not recognized when the tables were developed. Until better analysis of the fouling problem is developed, the fouling factors should be selected from Tables 24 and 25, which are abstracted from the TEMA tables [2].

Table 24. TEMA recommended fouling factors for waters[2]

Types of water	Fouling factor $\times 10^{-4}$ m^2 K/W			
	Heating-Medium Temp. $\leq 115\,^\circ$C Water Temp. $\leq 50\,^\circ$C		115 – 205 °C $> 50\,^\circ$C	
	Velocity ≤ 0.9 m/s	> 0.9 m/s	Velocity ≤ 0.9 m/s	> 0.9 m/s
Seawater	0.88	0.88	1.76	1.76
Brackish water	3.52	1.76	5.28	3.52
Cooling tower				
Treated makeup	1.76	1.76	3.52	3.52
Untreated	5.28	5.28	8.81	7.04
City or well water	1.76	1.76	3.52	3.52
River water:				
Minimum	3.52	1.76	5.28	3.52
Average	5.28	3.52	7.04	5.28
Muddy or silty	5.28	3.52	7.04	5.28
Hard ($>$ 15 grains/gal) (= 257 g/m^3)	5.28	5.28	8.81	8.81
Engine jacket	1.76	1.76	1.76	1.76
Distilled or closed-cycle condensate	0.88	0.88	0.88	0.88
Treated boiler feedwater	1.76	0.88	1.76	1.76
Boiler blowdown	3.52	3.52	3.52	3.52

Table 25. TEMA recommended fouling factors for fluids [2]

Symbols

V_H(kg/h)	heating steam flow rate
h_H(kJ/kg)	enthalpy of vaporization of the heating steam
t_H(°C)	condensing temperature of the heating steam
Δt_H(°C)	temperature drop for the heating steam condensate
p_H(Pa)	pressure of the heating steam
F (kg/h)	fresh solution feed rate
h_F(kJ/kg)	enthalpy of the fresh solution feed
t_F(°C)	inlet temperature of the fresh solution feed
ξ_F(wt %)	dissolved solids content of the fresh solution feed
D (kg/h)	solvent vapor flow rate
p (Pa)	pressure in the evaporator vapor separation chamber
h_D(kJ/kg)	enthalpy of the evaporated solvent
t_C(°C)	temperature in the evaporator vapor separation chamber
t (°C)	boiling point of pure solvent at pressure p
τ (°C)	boiling point rise for the solution at evaporator conditions
τ' (°C)	boiling point rise for salt solutions
τ^+ (°C)	boiling point rise due to hydrostatic head and pressure drop
ξ_C(wt %)	dissolved solids content of the concentrated solution
h_C(kJ/kg)	enthalpy of the concentrated solution
Q_L(kJ/h)	heat loss rate
c_H(kJ kg^{-1} K^{-1})	specific heat of the heating steam condensate
t_{WH}(°C)	temperature of the wall surface under the condensate film
z	number of ions into which a dissolved molecule dissociates
a	fraction of dissociated molecules in a solution with concentration ξ at the boiling point t of the pure solvent at operating pressure p
μ_s(kg/kgmol)	molecular mass of the solute
r_a(kJ/kg)	heat of vaporization of the solution
r_L(kJ/kg)	heat of vaporization of the pure solvent

1. Separating Substances by Evaporation

Solutions consisting of a solvent and dissolved solid substance may undergo simple thermal separation by vaporizing the solvent, thus concentrating the residual solid. This is a result of the vanishingly small vapor pressure of most solid components. This method plays an impor-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.b03_03

tant part in the recovery of many common materials, for example, polymers, salts and the like. Evaporation may also serve the purpose of separation and recovery of the pure solvent. It is also possible to use evaporation to concentrate emulsions and suspensions. Usually, the term *vaporization* is used when the predominant purpose is recovering the solvent and the term *evaporation* when the task is separating the solid or increasing its concentration.

Solvent vaporization takes place by reducing the pressure above a hot boiling solution. This principle finds broad industrial application in evaporating highly corrosive solutions, particularly in separation processes using evaporative crystallization. For solutions of crystallizable solids, vaporizing the solvent leads inevitably to supersaturating the solute and precipitating crystals from the solution. Solvent vaporization through pressure reduction or flash vaporization finds frequent use in industrial vacuum crystallization processes.

In designing evaporation plants, particularly in the choice and design of the equipment, a series of points needs careful consideration: chief among these is the operational behavior of the materials being processed, for example, any tendency toward forming deposits and fouling the heating surfaces, or the residence time of thermally unstable products.

2. Types of Evaporators and their Energy Consumption

2.1. Single Stage Evaporators

Energy consumption is determined by preparing the material and energy balances. To assist in illustrating and explaining the relationships, Figure 1 shows an equipment sketch of a calandria-type evaporator together with the symbols most often used for schematic evaporator representation. The evaporator consists of a vertically arranged cylindrical vessel with two horizontal tube sheets built into the lower half. The tube sheets support vertical heat exchange tubes. Steam condensing on the outside of the tubes brings the liquid in the tubes to boiling. Vapor bubbles formed within the tubes discharge, mixed with liquid, from the top of the tubes, promoting a natural recirculating fluid flow regime. A large vertical pipe is located in the center of the tube bundle to provide for the necessary downflow of unvaporized solution.

The vapors produced separate from liquid in the upper section of the evaporator and, when necessary, flow through special internal separating devices to remove entrained liquid droplets. A condenser or preheater condenses the vapors to liquid.

Dry saturated or slightly superheated steam is introduced outside the tubes below the upper tubesheet into the "stream chest". If the increase in the boiling point of the solution at the bottom of the tubes caused by the hydrostatic pressure due to the column of liquid is neglected, then the temperature difference between the heating steam and boiling liquid is practically constant along the length of the tube wall. Heat exchange in this evaporating equipment is thus characterized by practically no change in temperature of the evaporating and condensing media. This is not true for other evaporator constructions employing once-through flow. In these, the boiling temperature increases along the length of the vaporizing surface due to increase in solvent concentration. Once-through designs include falling film and thin film evporators. Also, vaporizers heated through the sensible heat of hot liquids show varying temperature differences between the cold and hot fluids along the length of the vaporizing surface.

The vapor pressure of the solvent in equilibrium with a solution is less than that of the pure solvent at the same temperature. This increases the boiling point of the solution. The boiling point rise τ is defined as the difference between t_C, the temperature in the evaporator vapor separation chamber, and t, the boiling point of pure solvent at pressure p. The heating steam condensate suffers a drop in temperature in the steam chest. It leaves the steam chest at the temperature $(t_H - \Delta t_H)$. The concentrated solution leaves the evaporator at $(F-D)$ flow rate, enthalpy h_C, temperature $(t+\tau=t_C)$, and ξ_C solids content. Equation (1) gives the solvent vapor rate evaporated from a feed, F, at initial composition, ξ_F, when concentrated to ξ_C:

$$D=F\left(1-\frac{\xi_F}{\xi_C}\right) \tag{1}$$

The heat balance Equation (2) gives the necessary heating steam rate:

Figure 1. Calandria type evaporator and evaporator symbolic diagram

$$V_{\mathrm{H}} = \frac{D\,(h_{\mathrm{D}} - h_{\mathrm{c}}) + F\,(h_{\mathrm{c}} - h_{\mathrm{F}}) + Q_{\mathrm{L}}}{h_{\mathrm{H}} - c_{\mathrm{H}}\,(t_{\mathrm{H}} - \Delta t_{\mathrm{H}})} \tag{2}$$

The quantity Δt_{H} may be determined from a relation by KIRSCHBAUM applying to steam heated equipment with vertical heating surfaces so long as the steam condenses on the surface in the form of a liquid film:

$$\Delta t_{\mathrm{H}} = 0.55\,(t_{\mathrm{H}} - t_{\mathrm{WH}}) \tag{3}$$

Equation (4) may be used to calculate the boiling point rise τ' of a salt solution, insofar as it results from the solute content:

$$\tau' = 8.3\,(1 + (z-1)\,a)\,\frac{\xi}{100-\xi}\,\frac{(273+t)^2}{\mu_{\mathrm{s}} r_{\mathrm{a}}} \tag{4}$$

For dilute solutions, r_{a} is set approximately equal to r_{L}, the heat of vaporization of the solvent. Depending on the tube length and hydraulic behavior, a boiling point increase τ^+ results due to the hydrostatic head of the solution as well as the pressure drop arising from flow through the tube. The total boiling point rise τ results as the sum:

$$\tau = \tau' + \tau^+ \tag{5}$$

From Equation (1) and Figure 2 follows that, in simple, single-stage evaporators, most of the heat content of the vaporized solvent is lost when condensing the residual vapors not used for feed preheating, in a separate condenser. Therefore, in the absence of measures for improving efficiency, the consumption of heating steam is comparatively high. In evaporating aqueous solutions, the ratio of heating steam to vapors generated amounts to about 1.2. Efficiency improvement measures can reduce this ratio considerably. Such measures may include advantageous local operating circumstances, integrating an evaporation stage into the energy balance for a complete process, or so-called *heat pumping* schemes to be described below.

Figure 2. Single-stage evaporator system

A small efficiency improvement, of the order of 10 – 15 %, is possible through preheating the fresh feed solution by condensing a small

portion of the vaporized solvent. Figure 2 is a schematic diagram of a process for achieving this result. In Figure 2, a small portion of the vaporized solvent preheats the feed by condensing in the preheater. A cooling medium condenses the residual vapors in the condenser.

Because of their low thermal efficiency, simple single-stage evaporators are seldom used. Their application is limited to systems of small capacity or those in which the product requires short solution residence time due to temperature sensitivity.

Figure 3. Heating steam consumption as a function of the number of stages *N*

2.2. Multistage Evaporation

Multistage evaporation is an effective means for reducing the steam consumption. A number of evaporator stages are connected together in such a manner that the solvent vapors generated in one stage serve as the heating medium for a succeeding stage. Also, only the vapors generated in the last stage must be condensed by a cooling medium, thus reducing cooling-water usage. Figure 3 is a representation of a potential efficiency improvement as a result of using multistage evaporation. The plant capital cost increases approximately linearly with the number of stages. Thus, for a given set of economic and operating circumstances, there exists an optimum number of evaporator stages for a given difference between the heating steam temperature in the first stage and the boiling temperature in the last stage. This optimum results in a minimum in the sum of costs due to capital charges and operating expenses. Moreover, the difference between the heating steam temperature in the first stage and the boiling temperature in the last stage sets a practical limit to the number of evaporator stages. For example, in the case of evaporators hydraulically dependent on natural circulation as shown in Figure 1, too small a difference in temperature between the hot condensing side and the boiling liquid side may inhibit uniform, steady state circulation. The boiling point rise tends to reduce even more the temperature difference between hot and boiling sides.

Three fundamental variants of multistage evaporator arrangements are possible. The relative direction of flow of steam or solvent vapors versus that of the solution serves to differentiate them. The method most frequently used in practice is so-called cocurrent flow feeding. In this, the feed solution is pumped into the stage at highest pressure first. Then the solution flows from stage to stage one after another without pumping, in the same direction as the solvent vapor using the stage to stage difference in pressure. The concentrated product leaves the system from the last, lowest pressure stage. In contrast, for countercurrent flow feeding, the fresh feed solution enters the stage at lowest pressure and is pumped from stage to stage to that at highest pressure. Solvent vapors flow in the opposite direction. Concentrated solution leaves the system from the evaporator at highest pressure and temperature. In the third arrangement, the fresh feed solution is divided into separate streams, with each stream feeding directly to a stage in parallel with the others.

Accordingly, the cocurrent flow feeding arrangement needs only a single solution pump. In operation, control is the simplest. The last

evaporator stage operates at the lowest temperature. This is a special advantage when evaporating solutions that become more temperature sensitive with increasing concentration. On the other hand, countercurrent flow feeding offers the advantage that the highly concentrated solution vaporizes in the stage at the highest temperature. There its viscosity is lower and the heat transfer rate is thereby better than would be the case in cocurrent flow feeding. For countercurrent flow feeding several liquid pumps are required. This means plant operations might be more prone to upsets than would be the case for cocurrent flow feeding. In practice, the third arrangement, splitting the feed, is used in those cases where, on evaporation, the solubility limit is exceeded, thus crystallizing out the solid material. It may also be used when concentrating a large feed flow for which exposure for only a short residence time is permitted.

Cocurrent flow feeding of steam and solution is the method predominantly used in practice. Figure 4 shows details of one possible arrangement for this process concept and the nomenclature for it. The nomenclature is an extension of Figure 1, and in the nomenclature listing the subscript n designates the stage number. Figure 4 shows condensate removal from the steam chest of each stage. The scheme provides several preheaters for multistage preheating of the fresh feed solution, each preheater using a portion of the solvent vapors generated in the respective evaporator stage.

The derivation of the relationships for determining the steam consumption result from material and energy balances across the thermodynamic boundaries of the total system and the subsystems comprising its parts. Since the assumption of steady-state operation applies, the net summations of mass and energy flows across system boundaries equal zero, i.e., total inflow of mass or heat across a boundary is equal to total outflow. From such balances around stages $1-n$, Equation (6) results for the solvent vapors from the nth stage:

$$\begin{aligned} &D_{\mathrm{n}}\left(h_{\mathrm{D}n}-h_{\mathrm{L}n}\right) \\ &=V_{\mathrm{H}}\left\{h_{\mathrm{H}}-c_{\mathrm{H}}\left(t_{\mathrm{H}}-\Delta t_{\mathrm{H}}\right)\right\} \\ &-D_1\left\{c_1\left(t_1-\Delta t_1\right)-h_{\mathrm{L}n}\right\} \\ &-D_{n-1}\left\{c_{n-1}\left(t_{n-1}-\Delta t_{n-1}\right)-h_{\mathrm{L}n}\right\} \\ &-V_1\left\{h_{\mathrm{D}1}-c_1\left(t_1-\Delta t_1\right)\right\} \\ &-V_{n-1}\left\{h_{Dn-1}-c_{n-1}\left(t_{n-1}-\Delta t_{n-1}\right)\right\} \\ &-F\left(h_{\mathrm{L}n}-h_{\mathrm{F}}\right)-Q_{\mathrm{L}1}\ldots-Q_{\mathrm{L}n} \end{aligned} \tag{6}$$

Using the nomenclature from Figure 4, the required withdrawal of solvent vapor for preheating the nth preheater by Equation (7) is calculated. In Equation (7), Δt_n designates the drop in condensate temperature on the heating side of preheater n:

$$V_n = F\frac{h_{\mathrm{F}n-1}-h_{\mathrm{F}n}}{h_{\mathrm{D}n}-c_n\left(t_n-\Delta t_n\right)} \tag{7}$$

Analogous to Equation (1), Equation (8) permits calculating the total solvent vapor removed from the solution in the n stages to achieve a desired final concentration:

$$\begin{aligned} &\sum_{n=1}^{n=N} D_n = D_1+D_2+\ldots\ldots D_n+\ldots\ldots D_N \\ &= F\left(1-\frac{\xi_{\mathrm{F}}}{\xi_{\mathrm{C}}}\right) \end{aligned} \tag{8}$$

On assuming a set of temperature and corresponding concentration distributions for the individual stages, substituting the numerical values of enthalpies, temperatures, concentrations, and flows into Equations (6) and (7) allows calculation of D_n as a function of V_{H}:

$$D_n = f_n\left(V_{\mathrm{H}}\right) \tag{9}$$

Then, Equation (8) permits determination of V_{H} for the selected distributions. This procedure may be applied to other multistage evaporator configurations in an analogous manner.

Equation (10) defines the effective temperature difference, the difference between the first stage heating medium (the stage operating at highest pressure) and the boiling solution in the last stage (the stage operating at lowest pressure) reduced by the sum of all boiling point elevations according to Equation (5):

$$\Delta t_{\mathrm{eff}} = t_{\mathrm{H}} - t_{\mathrm{N}} - \sum_{n=1}^{n=N} \tau_n \tag{10}$$

This effective temperature difference obviously sets limits to the usable number of stages N in a multistage evaporator plant. Since this total temperature difference must be allocated over the n stages and since the boiling point elevations reduce the temperature differences effective for heat transfer, a large increase in the total

Figure 4. Three-stage evaporator system with cocurrent flow of liquid and vapor

heat transfer area for the evaporator calandria becomes necessary. Equation (11) expresses the relationship between the heat transferred in a stage Q_n, the transfer coefficient k_n, the area A_n, and the temperature differences:

$$Q_n = k_n \cdot A_n \left(t_{\mathrm{H}} - t_{\mathrm{N}} - \sum_{n=1}^{n=N} \tau_n \right) / N \tag{11}$$

A large number of stages leads to small temperature differences. For evaporators operating with natural circulation arising from a thermosiphon effect, a certain minimum temperature difference is necessary in every stage to achieve stable hydraulic conditions. If not, vapor bubble formation becomes unstable and natural circulation ceases. Thus, in multistage systems with natural circulation evaporators, the maximum possible number of stages is determined by the effective total temperature difference and the minimum permissible temperature difference in a stage. The latter lies roughly between 10 – 20 °C. For highly viscous liquids, it may take on even higher values. If a pump forces the liquid circulation in the evaporator equipment, then the temperature difference in a stage may be held as small as is desired. Then, its optimal value, and thus also the optimum number of stages, must be determined by detailed economic studies. This becomes necessary due to the fact that energy costs do indeed decrease as the number of stages increases. However, the capital costs are higher.

For equally sized heat-exchange surfaces A_n, in all stages, Equation (12) shows the relationships for allocating the total temperature difference among the stages. Equation (13) for the scheme in Figure 4 applies for Q_n, the heat transferred in a stage:

$$t_{n-1} - (t_n + \tau_n) = \frac{\frac{Q_n}{k_n}}{\sum\limits_{n=1}^{n=N} \frac{Q_n}{k_n}} \cdot \left(t_{\mathrm{H}} - \left(t_N + \sum_{n=1}^{n=N} \tau_n \right) \right) \tag{12}$$

$$\begin{aligned} Q_n &= (D_{n-1} - V_{n-1}) \\ &\{h_{\mathrm{D}n-1} - c_{n-1}(t_{n-1} - \Delta t_{n-1})\} \\ &+ (D_1 + D_2 + \ldots + D_{n-2}) \\ &\{c_{n-2}(t_{n-2} - \Delta t_{n-2}) - c_{n-1}(t_{n-1} - \Delta t_{n-1})\} \end{aligned} \tag{13}$$

Apportioning the total temperature difference among the stages to result in equal heat-transfer surface in each stage does not, however, always lead to the most economical system. For example, if it is necessary to use expensive materials of construction, then it may be more advantageous to choose the temperature differences so that the total heat transfer surface for the evaporator system results in a minimum. This leads to Equation (14), which, like Equation (12), can only be solved iteratively:

$$t_{n-1} - (t_n + \tau_n) = \frac{\sqrt{\frac{Q_n}{k_n}}}{\sum_{n=1}^{n=N} \sqrt{\frac{Q_n}{k_n}}} \left[t_{\mathrm{H}} - \left(t_N + \sum_{n=1}^{n=N} \tau_n \right) \right] \tag{14}$$

Frequently, in fixing the boiling temperatures, the thermal instability of the feed requires consideration. Or, allowance must be made for the fact that, with increasing temperature, many products agressively corrode the heat-transfer surfaces.

Equation (15) is recommended for making a rough estimate of the heating steam consumption:

$$V_{\mathrm{H}} = \frac{\sum_{n=1}^{n=N} D_n}{\Delta h_{\mathrm{H}}} \left(\Delta h_{\mathrm{m}} - \Delta h_1 \cdot \frac{N-1}{N} \right) \tag{15}$$

$$\Delta h_{\mathrm{m}} = \frac{F\,(h_{\mathrm{L1}} - h_{\mathrm{F}})}{\sum_{n=1}^{n=N} D_n} + \frac{1}{1 + 0.01 \cdot N} \Delta h_1 \tag{16}$$

where

Δh_{H} = heat of condensation of the heating steam

Δh_{l} = heat of condensation of the solvent vapors from the first stage

Δh_m = average heat of vaporization according to Equation (16)

h_{F} = enthalpy of the feed solution to the first stage

h_{L1} = enthalpy of the solution boiling in the first stage

2.3. Evaporation with Vapor Recompression

Vapor-recompression evaporation is a heat-pumping technique. A portion, or the total flow of solvent vapor leaving the evaporator vapor separation chamber, is compressed to a higher pressure and condensed in the steam chest of the same evaporator. In many cases, this processing scheme achieves specific heating steam efficiencies that can only be attained by multistage evaporator systems having as many as three to five stages. One may use steam jet ejectors operated by high pressure steam to compress the solvent vapors. Or this can be done mechanically with centrifugal compressors, or, in exceptional cases, with positive displacement machines. In all cases, the steam or energy consumption for operating the compressor increases greatly with an increase in the temperature difference between the condensing compressed vapors and the boiling solution being evaporated. Solutions having high boiling point elevation cannot economically be concentrated by vapor recompression.

Setting the temperature difference required for heat transfer in the evaporator results from economic studies. These determine the minimum sum of operating costs and capital charges for the evaporator system. The most economical temperature difference between condensing heating vapors and boiling liquid usually lies in the range of about 10 – 20 °C. In general, the capital cost of vapor recompression systems using electrically driven compressors is higher than for multistage systems. Occasionally, a combination of both schemes may be used.

A single-stage evaporator permits selecting a relatively low boiling temperature, one attainable, usually, only in the last stage of multistage systems. Thus evaporation with heat recovery through vapor recompression often represents the sole possibility for concentrating temperature-sensitive solutions economically at the lowest possible boiling temperature. The field of application for vapor recompression is thus definitely in the area of products requiring lower boiling temperatures.

Figure 5 schematically shows compressing the solvent vapors by using thermal compression. A steam jet ejector driven by high pressure inlet steam draws in the evaporated solvent vapor and exhausts at a pressure sufficiently high that it supplies the necessary evaporator heating steam. The steam jet ejector consists of the body with inlet flange and steam nozzle and the mixing nozzle with diffusor. Since it is simple and has no moving parts, its operation is free of breakdowns and its purchase cost is low. In addition, the choice of materials of construction is not limited. However, the efficiency of new units is low and, in operation, usually becomes lower due to steam nozzle erosion, which is caused by

water droplets in the drive steam. Figure 5 also defines the nomenclature for the symbols used in the following description.

Figure 5. Evaporator with steam jet ejector

Drive steam at a pressure greater than that in the evaporator enters the steam nozzle. It expands isentropically to the pressure in the mixing nozzle, drawing in and mixing with evaporated solvent vapors. The combined drive steam and solvent vapor together flow through the diffusor, which converts the kinetic energy of velocity back again into the potential energy of pressure. Finally, combined drive steam and solvent vapor leave the diffusor and enter the evaporator steam chest at a pressure below that of the drive steam but above that of the evaporator vapor separation chamber.

To determine the fraction of the total heating steam V_{H} represented by drive steam V_{T} and by solvent vapor V_{K}, a performance chart for the particular ejector is used–Figure 6 represents a typical example. Figure 6 shows the pumping behavior of a steam jet ejector. The dependence of the entrainment ratio

$$\varphi = \frac{V_{\mathrm{K}}}{V_{\mathrm{T}}} \tag{17}$$

is plotted as a function of solution boiling point (or evaporator pressure) at fixed steam chest pressure (or heating steam condensing temperature) with parameters of drive steam pressure. Then, by material balance, Equation (18) gives the flow of heating steam, Equation (19) the drive steam for the steam jet ejector or the net heating steam, and Equation (20) the compressed solvent vapor rate:

$$V_{\mathrm{H}} = V_{\mathrm{T}} + V_{\mathrm{K}} = V_{\mathrm{T}}\,(1+\varphi) \tag{18}$$

$$V_{\mathrm{T}} = V_{\mathrm{H}}\,\frac{1}{1+\varphi} \tag{19}$$

$$V_{\mathrm{K}} = V_{\mathrm{H}}\,\frac{\varphi}{1+\varphi} \tag{20}$$

Figure 6. Entrainment ratio as a function of the boiling point

The flow of heating steam required for the specified evaporation is known from Equation (2). Then the entrainment ratio is read from Figure 6 for the evaporator temperature, and the drive steam rate is calculated from Equation (19) and the solvent vapor flow from Equation (20).

From energy efficiency considerations, steam jet ejectors are more favorable for vapor recompression in the area of lower working pressures. The higher flow rates, above 5000 $\mathrm{Nm^3/h}$, are the field of application for centrifugal compressors. Not only electric motors but also steam turbines serve for the drive equipment. Figure 7 shows a process schematic along with nomenclature for a vapor recompression process using an electrically driven compressor. The auxiliary heating is necessary for startup. However, it is also needed during operation for the case where the compressed solvent vapors do not suffice. This occurs when feeding relatively cold solution.

The schematic enthalpy – entropy diagram shown in Figure 7 assists in defining the compressor performance. Simplifying assumptions

Figure 7. Evaporator with vapor compressor

are that the solvent vapors are dry and saturated and that the compression requires only a single stage. A theoretically reversible isentropic compression would follow the dotted path 1 – 2′ with isentropic enthalpy change Δh_{AK}. The real compression follows the solid line polytropic path 1 – 2 with discharge enthalpy h_{H} resulting from Equation (21):

$$\Delta h_{\mathrm{AK}} = (h_{\mathrm{H}} - h_{\mathrm{D}}) \cdot \eta_{\mathrm{iK}} \tag{21}$$

where η_{iK} is the indicated isentropic gas efficiency. Designating η as the total efficiency (including mechanical inefficiencies) allows expressing the compressor total power consumption N_{K} (kW) by equation (22):

$$N_{\mathrm{K}} = \frac{1}{3600} \cdot \frac{\Delta h_{\mathrm{AK}} \cdot V_{\mathrm{H}}}{\eta} \tag{22}$$

Mechanical vapor recompression with an electrically driven compressor is then economical only if the temperature difference ϑ between the condensing compressed vapor and the boiling solution can be kept small, and a single-stage compressor suffices. Usually, this means that ϑ must be less than 20 °C, which is the case only for solutions having low boiling-point elevation.

Figure 8 shows a schematic diagram for vapor recompression using a steam turbine driven compressor. The compressed solvent vapors and the turbine drive steam exhaust to the same pressure, that of the steam chest. The heating steam flow V_{H} is the sum of the two flows. Also given in Figure 8 is a schematic Mollier enthalpy – entropy diagram, which qualitatively shows the changes in state for the steam flows. The evaporated vapors are assumed to be practically dry and saturated, permissible when the boiling point rise is small. Moreover, both expansion in the turbine as well as compression are assumed to be single stage.

Theoretically reversible isentropic expansion of the superheated drive steam from p_{T} to p_{H} would follow the dotted path a – b′ with isentropic enthalpy change Δh_{AT}. Likewise, theoretically reversible isentropic compression of the evaporated vapors from p to p_{H} would follow the dotted path c – d′ with isentropic enthalpy change Δh_{AK}. Actually, both expansion and compression are polytropic, following the paths a – b with enthalpy drop Δh_{T} and c – d with enthalpy rise Δh_{K}, respectively. For indicated isentropic gas efficiencies η_{iT} for the turbine and η_{iK} for the compressor, the enthalpy of the expanded drive steam h_{b} is:

$$h_{\mathrm{b}} = h_{\mathrm{T}} - \eta_{\mathrm{iT}} \cdot \Delta h_{\mathrm{AT}} \tag{23}$$

and that for the compressed vapor h_{d} is:

$$h_{\mathrm{d}} = h_{\mathrm{D}} + \frac{\Delta h_{\mathrm{AK}}}{\eta_{\mathrm{iK}}} \tag{24}$$

From these, Equation (25) gives the enthalpy of the mixed vapor:

$$h_{\mathrm{H}} = \frac{V_{\mathrm{T}} h_{\mathrm{b}} + V_{\mathrm{K}} h_{\mathrm{d}}}{V_{\mathrm{H}}} \tag{25}$$

Once again, Equation (2) gives the flow of heating steam V_{H}, composed of drive steam

Figure 8. Evaporator with steam turbine driven vapor compressor

and compressed evaporated vapors, required to achieve the specified evaporation. Equations (25) and (26) are then solved simultaneously giving equations (27) and (28) for calculating V_{T}, the drive steam flow, and V_{K}, the compressed vapor flow. η_{K} and η_{T} are the respective total efficiencies of compressor and turbine determined as the products of the respective indicated gas and mechanical efficiences:

$$V_{\mathrm{K}} - \frac{\Delta h_{\mathrm{AK}}}{\eta_{\mathrm{K}}} = V_{\mathrm{T}} \eta_{\mathrm{T}} \Delta h_{\mathrm{AT}} \tag{26}$$

$$V_{\mathrm{T}} = \frac{V_{\mathrm{H}} \Delta h_{\mathrm{AK}}}{\Delta h_{\mathrm{AT}} \eta_{\mathrm{T}} \eta_{\mathrm{K}} + \Delta h_{\mathrm{AK}}} \tag{27}$$

$$V_{\mathrm{K}} = V_{\mathrm{H}} \frac{\eta_{\mathrm{T}} \eta_{\mathrm{K}} \Delta h_{\mathrm{AT}}}{\eta_{\mathrm{T}} \eta_{\mathrm{K}} \Delta h_{\mathrm{AT}} + \Delta h_{\mathrm{AK}}} \tag{28}$$

Given values of η_{T} and η_{K}, and with the help of the Mollier diagram, Equation (29) allows determination of h_{H}, the enthalpy of the heating steam:

$$h_{\mathrm{H}} = \frac{\Delta h_{\mathrm{AK}}}{\eta_{\mathrm{T}} \eta_{\mathrm{K}} \Delta h_{\mathrm{AT}} + \Delta h_{\mathrm{AK}}} \cdot \left(h_{\mathrm{b}} + h_{\mathrm{d}} \eta_{\mathrm{T}} \eta_{\mathrm{K}} \frac{\Delta h_{\mathrm{AT}}}{\Delta h_{\mathrm{AK}}} \right) \tag{29}$$

Then, Equation (2) is used to calculate the required flow of heating steam V_{H}; Equation (27), the drive steam flow for the turbine V_{T}; and Equation (28) is used to calculate V_{K}, the flow of compressed evaporated vapors.

Vapor recompression results in significant energy savings. Specific consumption of drive steam d, the net steam required, may be as low as 0.3.

$$d = V_{\mathrm{T}} / D$$

Economically justifiable operating temperatures can be as low as about $t_{\mathrm{C}} = 50\,^{\circ}\mathrm{C}$, and temperature differences between condensing heating steam and boiling solution ϑ is $10 - 20\,^{\circ}\mathrm{C}$.

According to the definition of the problem and the operating conditions, evaporator systems using vapor recompression may require auxiliary condensers or heaters. To the extent that the specified evaporation requirements produce more total solvent vapor than can be compressed and condensed in the steam chest, given the turbine and compressor efficiencies and initial pressure and superheat of the drive steam, an auxiliary condenser is needed. Likewise, if the total compressed solvent vapor plus drive steam does not suffice for the specified evaporation requirements, then the deficiency must be met with auxiliary heating.

For a plant with motor driven compressor, in the limiting case where neither auxiliary condensing or heating is required, the compressed evaporated solvent vapor flow V_{K} must equal the required steam flow rate D. Equation (30) applies to this limiting case:

$$(h_{\mathrm{F}})_{D=V_{\mathrm{K}}} = h_{\mathrm{C}} - \left(1 - \frac{\xi_{\mathrm{F}}}{\xi_{\mathrm{C}}}\right) \cdot \left[\{h_{\mathrm{H}} - c_{\mathrm{H}} (t_{\mathrm{H}} - \Delta t_{\mathrm{H}})\} \left(1 + \frac{1}{\varphi}\right) - (h_{\mathrm{D}} - h_{\mathrm{C}}) \right] \tag{30}$$

The probability of needing an auxiliary condenser is substantially greater if the solvent vapor compression is effected with a steam jet ejector or a steam turbine driven compressor than when an electrically driven unit is used.

With electrically driven compressor units, auxiliary heating is often necessary. For this case, one may calculate the auxiliary steam V_z needed with Equation (31):

$$V_Z = V_H \left\{ 1 - \frac{h_H - c_H\,(t_H - \Delta t_H)}{h_D - h_C + \frac{h_C - h_F}{1 - \xi_F/\xi_C}} \right\} \tag{31}$$

If the calculation results in a negative value for V_z, then auxiliary heating is unnecessary, but an auxiliary vapor condenser is required. In that case, the portion of the evaporated solvent that must be condensed, V_R, is:

$$V_R = D - V_H = -V_Z \tag{32}$$

However, in both the above cases, and all other cases when needed, evaporator startup requires auxiliary heating until a sufficient flow of solvent vapor for the compressor is produced. In the case of evaporated vapor compression using a steam jet ejector or steam turbine driven compressor, where it is not possible to dispense with auxiliary heating, the relationship giving the addition flow of steam required is Equation (33) with the pumping ratio $\varphi = V_K/V_T$ given by Equation (34):

$$V_Z = V_H \left\{ 1 - \left(1 + \frac{1}{\varphi}\right) \frac{h_H - c_H\,(t_H - \Delta t_H)}{h_D - h_C + \frac{h_C - h_F}{1 - \xi_F/\xi_C}} \right\} \tag{33}$$

$$\varphi = \eta_T \eta_K \frac{\Delta h_{AT}}{\Delta h_{AK}} \tag{34}$$

2.4. Optimizing Evaporation Systems

An economically optimal evaporator system is the result of a project engineering effort that always strives to minimize the total cost, which is made up of investment costs and operating costs. In this way, the optimal number of stages N_{opt} is found for a project-engineering multistage evaporator system. If the design of a multistage evaporator system requires expensive materials of construction to avoid corrosion, this may then, in the design, fix a need to minimize total heating surface (see Section 2.2). This additional optimization parameter must then be taken into consideration in the aforementioned evaluation procedures for determining the optimal number of stages.

Figure 9. Evaporation by reduced pressure flashing
A: Without liquid circulation; B: liquid circulation

If the temperature difference in a particular stage is insufficient to provide a natural, thermosiphon circulation, then the liquid circulation in the evaporators can be forced by installing pumps. This forced circulation leads to considerable improvement in heat transfer with increasing liquid velocity, and thus reduction in heat transfer surface. The optimal circulation velocity is that resulting in minimum total cost.

In the case of vapor recompression with an electrically driven compressor, the necessary energy for compression increases with increasing difference in temperature between the condensing heating vapors and the boiling solution, $\vartheta = t_H - t_C$. At the same time, however, the evaporator heating surface decreases. Consequently, there is an optimal temperature difference at which a minimal value in the total cost results.

The local conditions and specific energy costs at the erected location of an evaporation system may materially influence the results of optimization studies. For example, the cost of cooling water in itself may be a decisive factor.

2.5. Evaporation Using Pressure Reduction

Figure 9 A shows a flash vaporizer system consisting of a liquid heater, a separator drum for the flash vapors formed on expansion, and a vapor condenser. Frequently, this type of evaporation scheme is employed for solutions inclined toward forming deposits on or otherwise scaling or corroding the heat transfer surfaces. The nomenclature and units for the following discussion of the single-stage flash vaporizer in Figure 9 A generally follows previous usage.

The enthalpy of fresh feed at h_F* increases to h_F^+ in the vapor condenser and to h_F in the steam-heated liquid preheater. The throttle valve maintains the required pressure difference between the liquid preheater outlet and the flash separator drum, $(p_F - p)$. The vapors D produced in the flash separator drum condense in the vapor condenser. If the temperature drop for the condensed vapors or steam in the heat exchangers as well as any boiling point rise in the preheater is neglected, then only the latent heats Δh_H of the heating steam in the preheater and that of the vapors Δh_D in the condenser enter into consideration. Consequently, Equations (35) and (36) express the relationships for calculating the specific heating steam consumption from the enthalpies fixed by the job specification:

$$\frac{V_H}{D} = \frac{\Delta h_D}{\Delta h_H} \cdot \frac{h_F - h_F^*}{h_F^+ - h_F^*} = \frac{\Delta h_D}{\Delta h_H} \cdot \frac{h_F - h_F^*}{h_F - h_C} \tag{35}$$

or

$$\frac{V_H}{D} = \frac{\Delta h_D}{\Delta h_H} \cdot \frac{h_C - h_F^*}{h_F - h_C} \tag{36}$$

Equation (37) fixes the enthalpy h_F^+ to which the fresh feed can be warmed in the evaporated vapor condenser:

$$h_F^+ = h_F^* + h_F - h_C \tag{37}$$

The ratio of inlet steam consumption to evaporated vapor produced is substantially higher than that for a single-stage calandria heated evaporator. The reason is that the evaporated vapor D raised in the flash separator drum at relatively high feed liquid preheat, even above the boiling temperature itself, makes up only a fraction of the available liquid flow. Equation (38) gives this ratio:

$$\frac{D}{F} = \frac{h_F - h_C}{\Delta h_D} = \frac{h_F^+ - h_F^*}{\Delta h_D} \tag{38}$$

The concentration ratio

$$\frac{\xi_F}{\xi_C} = 1 - \frac{h_F - h_C}{\Delta h_D} \tag{39}$$

is comparatively unfavorable. Its best value is set by the maximum attainable feed liquid enthalpy h_F. Also, the feed liquid pressure upstream of the throttle valve depends on h_F.

To improve the concentration ratio for a single-stage flash vaporizer, an arrangement like in Figure 9 B is used. A pump is installed to recycle a partial flow of flashed liquid to mix with the fresh solution preheated in the vapor condenser. Thus, liquid flow through the preheater increases by the factor f:

$$f = \frac{F + U}{F} \tag{40}$$

By this means the flow of vapor evaporated by flashing is greater by the factor f than that without liquid recycle:

$$\frac{D}{F} = f \cdot \frac{h_F - h_C}{\Delta h_D} \tag{41}$$

Also, the fresh feed solution is heated in the vapor condenser to a higher enthalpy:

$$h_F^+ = h_F^* - f\,(h_F - h_C) \tag{42}$$

Equation (43) also defines the characteristic factor f, allowing calculation of the recycle flow by Equation (44) as well as the heating steam consumption by Equation (45)

$$\frac{V_H}{D} = \frac{\Delta h_D}{\Delta h_H} \cdot \frac{1}{f} \cdot \frac{h_C - h_F^*}{h_F - h_C} \tag{43}$$

$$U = F\,(f-1) \tag{44}$$

$$\frac{V_H}{D} = \frac{\Delta h_D}{\Delta h_H} \cdot \frac{1}{f} \cdot \frac{h_C - h_F^*}{h_F - h_C} \tag{45}$$

Corresponding to the greater flow of evaporated vapor in operation with liquid recycle, the concentrated solution has a higher solids concentration ξ'_C than that in operation without recycle, Equation (46), as well as achieving a more favorable concentration ratio, Equation (47)

$$\xi_C = \frac{\xi_C}{f - \frac{f-1}{\xi_F/\xi_C}} \tag{46}$$

$$\frac{\xi_F}{\xi'_C} = 1 - f \cdot \frac{h_F - h_C}{\Delta h_D} \tag{47}$$

The multistage principle may also be applied to flash vaporization to achieve better heat utilization. A series of evaporated vapor condensers preheats fresh feed solution to progressively higher temperatures by condensing evaporated vapors at progressively higher pressures. Inlet steam completes solution preheating, followed by successive stages of pressure reduction in flash separator drums, generating vapors at the pressures used in preheating. This brings the solution to progressively higher solids concentration. Recovery of potable water from sea water to a large extent makes use of this process of multistage flash vaporization. In contrast to multistage calandria evaporators, multistage flash vaporizers are notable for having no lower limit with respect to the temperature difference between two neighboring evaporator stages. Thus, at otherwise equal conditions, it is possible to build a flash vaporizer system with a substantially greater number of stages.

Relationships derived from heat and material balances also permit engineering energy calculations for multistage flash vaporizers. Figure 10 shows the unmistakably strong dependence of the energy requirement on the number of stages N, preheat temperature t_F, as well as the temperature difference ϑ_e between a flash vapor condensing temperature and the outlet feed liquid temperature of the respective condenser. With respect to energy conservation, then, systems with a large number of stages and thus higher seawater preheat are especially suited for economically producing potable water.

Figure 10. Heat consumption of reduced pressure flash evaporators as a function of number of stages, preheat temperature, and temperature difference

There are yet a number of other possible industrial applications of flash vaporizers. Thus, vacuum cooling units used in the potash industry employ this principle of operation. These serve to cool hot salt solutions by removing heat through partial autovaporization in a series of vacuum vessels operating at stagewise decreasing pressures.

3. Designing Evaporators for Fabrication

The decisive factors governing the selection of an evaporator design are the system capacity and the behavior of the feedstock from an operational viewpoint. For physically stable solutions with little tendency toward scaling and corrosion, few operational upsets should be expected, and comparatively simple and inexpensive equipment design would normally be employed. But for heat-sensitive materials that are easily decomposed, a relatively expensive unit having a short product residence time and designed to operate at as low vacuum as possible would be necessary. The properties of the substance, which are dependent on the pressure and temperature, as well as the vaporization behavior, in turn dependent on the concentration of the solution, determine the equipment design concept. Figure 11 shows some design concepts frequently employed:

11 A) Units with vertical evaporator tubes, heated on the outside, and having a central downcomer for natural thermosiphon liquid circulation, often referred to as calandria;
11 B) Units with vertical evaporator tubes, heated on the outside, contained in an external heat exchanger, also with external downcomer for natural thermosiphon or forced liquid circulation;
11 C) Units with sloping, or in the limiting case, horizontal evaporator tubes, heated on the outside, contained in an external heat exchanger, also with external downcomer for natural thermosiphon or forced liquid circulation;
11 D) Units with horizontal, internally heated evaporator tubes, immersed in the liquid, commonly referred to as kettles;
11 E) Units with vertical evaporator tubes, heated on the outside, for once-through liquid flow from bottom to top;
11 F) Units with vertical evaporator tubes, heated on the outside, for liquid flow from top to bottom, in accordance with the falling film principle;
11 G) Agitated film evaporators, vertical units equipped with rotating wiper blades for spreading the downward flowing liquid in an evenly distributed thin film on the inside surface of a large diameter, externally heated evaporator pipe. The pipe may be tapered. Sometimes, the units are horizontal;
11 H) Units with a rotating, externally heated, conical vaporizing surface, with liquid flowing upward in a thin film, evenly distributed by centrifugal force, often referred to as molecular stills of the Hickman type;
11 I) Units with no heating surface, consisting of a simple flash separator drum, for flash vaporization of preheated liquids.

While Types 11 A – C employ the same operating principle wherein the evaporation phenomenon is coupled with liquid circulation, the remainder of the units function differently, and there are fundamental differences among them. In Types 11 A – E, the vapor forms in the presence of a large flow of liquid. In contrast, in Types 11 F – H, vaporization occurs from a liquid film or a relatively thin layer. In Type 11 I, vaporizing the solvent is achieved by reducing the pressure on a preheated fresh solution.

The indicated differences relative to construction and manner of operation lead, in part, to diverse operating conditions. Thus, for example, an agitated thin film evaporator, Type 11 G, must operate with a higher temperature difference between heating medium and boiling liquid to achieve high vaporization capacity. The reason is a limitation of this construction in that a unit of given total volume can only accomodate a comparatively small heat exchanger surface.

Table 1 presents a brief overview of the suitability of the various vaporizer operating concepts for performing the tasks met in evaporation technology.

4. Design

4.1. Heating Equipment

In Types 11 A – E, the energy Q given up by the heating medium is imparted to the solution by heat transfer through the exchanger tube walls. For this, based on an expression for steady-state transfer of heat through circular walls with height H, inner diameter d_i, and outer diameter d_a, the following relationship applies:

$$Q = \frac{\pi H \vartheta}{\frac{1}{\alpha_\mathrm{V} d_\mathrm{a}} + \frac{1}{2\lambda_\mathrm{W}} \ln \frac{d_\mathrm{a}}{d_\mathrm{i}} + \frac{1}{a_\mathrm{L} d_\mathrm{i}}} \tag{48}$$

Figure 11. Evaporator types
See the text for the description of the various types.

Table 1. Operating characteristics of various types of evaporators

Type of evaporator	Viscosity, Pa s	Evaporative capacity	Tendency to salting and scaling	Holdup time
Natural circulation	0.05	small – large	great	very long
Forced circulation	1.0	small – large	less	very long
Climbing film	0.5	small – large	great	medium
Falling film	0.1	small	medium – great	short
Thin film	10 – 100	medium – large	slight	short
Flash	0.01	small – medium	slight	short – long

where

Q (J/s) = heat transferred
H (m) = tube length
d_i(m) = tube inner diameter
d_a(m) = tube outer diameter
ϑ (°C) = effective overall temperature difference between heating medium and solution on either side of the tube wall
λ_W(W m^{-1} K^{-1}) = coefficient of thermal conductivity
α_V(W m^{-2} K^{-1}) = film coefficient of heat transfer for the tube outer surface
α_L(W m^{-2} K^{-1}) = film coefficient of heat transfer for the tube inner surface
K (W m^{-2} K^{-1}) = overall coefficient of heat transfer based on the average tube surface
s_W(m) = tube wall thickness

For thin-walled heating surface of thickness s_W, the following relationship results from Equation (48):

$$Q = \frac{1}{\frac{1}{\alpha_V} + \frac{s_W}{\lambda_W} + \frac{1}{\alpha_L}} \cdot A \cdot \vartheta \tag{49}$$

For the case of an exchanger tube bundle with R tubes, Equation (50) gives the total heat transfer surface:

$$A = R \cdot \frac{d_i + d_a}{2} \cdot \pi \cdot H \tag{50}$$

Then the expression for the overall heat transfer coefficient K is:

$$K = \frac{1}{\frac{1}{\alpha_V} + \frac{s_W}{\lambda_W} + \frac{1}{\alpha_L}} \tag{51}$$

Equation (51) applies precisely for flat surfaces only. But it may be used for round, thin-walled evaporator tubes with sufficient accuracy for equipment design.

If scaling or severe salting of the tube surface is expected, a thermal conductivity resistance in the term s_W/λ_W must be incorporated in determining the overall heat transfer coefficient K. Scaling or salting of the tube surface usually causes severe deterioration in the heat transfer.

The sum of the thermal conductivity resistances s_W/λ_W and the reciprocals of the film coefficients $1/\alpha_V$ and $1/\alpha_L$ makes up the total thermal resistance $1/K$. Tables of values for λ_W are available for the usual materials used in exchanger fabrication. In general, however, one must calculate the film coefficients α_V and α_L, since they are dependent on the mechanical design of the particular unit and on the operating conditions. For rough estimations, a variety of average K values may be used.

Steam is the medium most often used for heating evaporators. The physical phenomenon is then a matter of virtually static, saturated steam condensing as a liquid film on a vertical heating surface with the height H. If this flows continuously as a laminar film on the wall, then one may calculate the film heat-transfer coefficient α_V for the steady state in accordance with the Nusselt film theory:

$$\alpha_V = K \sqrt[4]{\frac{\Delta h_V \cdot \varrho_K^2 \cdot \lambda_K^3 \cdot g}{\eta_K \cdot \vartheta_H \cdot H}} \tag{52}$$

where

Δh_v(J/kg) = latent heat of condensation of steam at the pressure in question
ϱ_K(kg/m^3) = density of the condensate film
λ_K(W m^{-1} K^{-1}) = thermal conductivity of the condensate film
η_K(kg m^{-1} s^{-1}) = dynamic viscosity of the condensate film

The value of the constant k in the equation is 0.943.

Frequently, however, the steam condenses on the wall in the form of droplets. For example, this may occur when the steam or the heat-transfer surface is contaminated with oil or grease. Then, the film heat-transfer coefficients may be about six to twenty times higher than those with pure film condensation. If the assumption that the steam is practically static is not admissible, then Equation (52) gives low numerical values. According to the Nusselt theory, the equation for the film heat-transfer coefficient α_V for flowing condensing saturated steam with the velocity u_V then changes in accordance with the relationship:

$$\alpha_V = K \sqrt[3]{\frac{C \cdot \Delta h_V \cdot \varrho_K \cdot \varrho_V \cdot \lambda_K^2 \cdot u_V^2 \cdot g}{\eta_K \cdot \vartheta_V \cdot H}} \tag{53}$$

Here, the constant is $C = 10.5 \times 10^{-4}$.

The saturated steam available in industry is usually contaminated with air or inert gases. This air impurity can lead to a severe adverse effect on the film heat transfer coefficient for condensation in heating equipment. Therefore, an important requirement in fabricating the evaporator heating element is an absolutely reliable means for venting inert gases from the steam chest.

The basic types of industrial evaporation equipment represented in Figure 11, in general, show varied high heat transfer coefficients for the boiling liquid. They vary in accordance with the operating conditions and the principles governing the particular boiling behavior. Without doubt, the nature and conditions for the hydraulic flow regime are determining factors for the film heat-transfer coefficient on the liquid side of the exchanger. Thus, in the case of recirculating and once-through vaporizers, the proportion of vapor admixed in the boiling liquid is a decisive factor. Then, according to whether nucleate or convection boiling takes place, distinct laws of physics and physical chemistry determine the film heat-transfer coefficient. The film heat-transfer coefficient α_L of the vaporizing solution can be represented as a function of characteristic design parameters of the equipment, values for the physical properties of the fluids, and the operating conditions. These are combined into various dimensionless numbers well known in the general heat-transfer and fluid-flow theory.

For the most part, industry is concerned with vaporizing flowing or moving liquids. For va-

Figure 12. The film heat-transfer coefficient for boiling water α_L as a function of temperature difference ϑ_L

porizing liquids at rest, the film heat-transfer coefficient of the boiling liquid α_L characteristically depends on the temperature difference ϑ_L between the wall temperature on the liquid side t_{WL} and the boiling temperature t_C. Figure 12 shows, for example, the behavior for boiling water at 0.1 MPa. Only occasionally is this behavior found in vaporizing flowing liquids in industrial equipment.

Representing heat transfer is made more difficult for vaporization in that one must deal, in general, with a combined single phase – two phase flow condition. Therefore, predictive calculation of the film heat-transfer coefficient according to the natural laws governing single-phase flow is limited only to special cases. For the most part, semi-empirical relationships are used. Equation (54) is a dimensionless relationship from KIRSCHBAUM, making possible predictive calculation of the film heat-transfer coefficient α_L for boiling liquids in natural circulation vaporizers, as in Figures 11 A and 11 B. It agrees well with measured values.

$$\frac{\alpha_L \cdot \sigma_L}{\lambda_L \cdot p} = c \cdot \frac{\vartheta_L \cdot c_L}{\Delta h} \left(\frac{\varrho_L}{10^3 \varrho_V}\right)^{0.5} \left(\frac{\eta_{H_2O}}{\eta_L}\right)^{0.25} \quad (54)$$

The factor c depends on the apparent liquid level h. The parameter h is the liquid holdup or liquid inventory in an exchanger tube, which is defined as the height of a column of clear liquid, expressed as a percentage of the tube length measured upward from the lower tube sheet of the exchanger, which would appear in a manometer connected between the lower channel of the exchanger and the liquid free vapor separation chamber. Empirically, one finds $c = 0.24$ at an apparent level $h = 75$ % and $c = 0.37$ at an apparent level $h = 40$ %.

Other nomenclature in Equation (54) is as follows:

σ_L(kg/m) = surface tension of the boiling liquid in contact with its vapor
λ_L(W m^{-1} K^{-1}) = thermal conductivity of the boiling liquid
c_L(J kg^{-1} K^{-1}) = liquid specific heat
Δh (J/kg) = latent heat of vaporization of the liquid
ϱ_L(kg/m^3) = density of the liquid
ϱ_V(kg/m^3) = density of the vapor in equilibrium with the liquid
η_L (kg m^{-1} s^{-1}) = dynamic viscosity of the fluid

In predictive calculation of the film heat-transfer coefficient α_L using Equation (54) the selected temperature difference ϑ_L should not be smaller than the least temperature difference necessary to stimulate natural circulation. This limiting temperature difference necessary to stimulate natural circulation may be taken from empirically derived limit curves. These curves are also necessary for design of multistage evaporators as they identify the relationships that limit the number of stages.

Figure 13 reproduces examples of such limit curves. They show the dependence of the appar-

ent liquid level h on the temperature difference ϑ_L between the inside tube wall temperature t_{WL} and the boiling temperature t_C with t_C as a parameter. These limit curves are typical of those showing operating points at which natural circulation just ceases. At operating conditions lying in the area below the curves, natural circulation will not automatically initiate nor continue if initiated at other conditions.

Figure 13. Natural circulation limit curves at various boiling temperatures

For evaporating solutions having severely corrosive characteristics, systems using comparatively expensive materials of construction for the heat-exchange surfaces must be designed. This sets a requirement for designing relatively small evaporator heat-exchanger elements. In turn, this may lead to a need for increasing the velocity of the recirculating, vaporizing liquid.

The Nusselt – Kraussold equation may be used for calculating the inside film heat transfer coefficient α_L for boiling liquid in tubes in forced circulation evaporators:

$$\alpha_L = 0.032 \frac{\lambda_L}{d_i} \left(\frac{u_L \cdot d_i \varrho_L}{\eta_i} \right)^{0.8} \left(\frac{c_L \cdot \eta_L \varrho_L}{\lambda_L} \right)^{0.37} \left(\frac{H}{d_i} \right)^{0.054} \tag{55}$$

Equation (55) applies when the liquid-side temperature difference $\vartheta_L = (t_{WL} - t_L) \leq 6\,°C$ and the Reynolds number exceeds 10 000; H denotes the tube length and d_i its inner diameter. Table 2 contrasts ranges of film heat-transfer coefficients commonly experienced in natural and forced circulation evaporators with one another.

Table 2. Overall coefficient of heat transfer for some modes of operation

Overall coefficient of heat transfer	k, W m^{-2} K^{-1}
Natural circulation, viscous solution	350 – 900
Natural circulation, mobile solution	600 – 1800
Forced circulation	900 – 2900

As compared to evaporators with vertical tubes, units with inclined tubes have the advantage that the liquid holdup can be held relatively low in proportion to the evaporator capacity, achieving the desired concentration for the recycle liquid in short residence times. Therefore, evaporation of temperature-sensitive solutions or materials inclined to discolor or precipitate deposits even at still higher temperatures is made possible. A further advantage over evaporators with vertical tube arrangements is that the construction results in a lesser liquid hydrostatic pressure in the tubes. In turn, a much lower boiling point rise results, which causes a substantially lesser deterioration in the total temperature difference in the evaporator system. Heat-transfer measurements have been made on operating evaporators not only with vertical but also inclined vaporizer tube arrangements. These show that inclined tube evaporators have substantially higher heat-transfer coefficients than those with vertical tubes. Figure 14 reproduces these measurements.

Figure 14. Heat-transfer coefficient in vertical and inclined tubes

Figure 11 D shows that kettle-type units, with horizontal heat exchanger tubes immersed in the liquid, have an advantage that a still lesser level of liquid suffices to envelop the tubes and wet them completely. As a result, the vaporizing liquid is under a low hydrostatic pressure and at a boiling temperature only slightly above

the saturated vapor temperature obtaining at the pressure in the vapor separation chamber. This type of unit is also able to operate comparatively well in vaporizing solutions that foam severely. The concept generally permits greater area for vapor – liquid release and allows better separation of entrained liquid droplets resulting from the bubbling and foaming than evaporators with vertical tube arrangements.

At small temperature differences, in kettle units, free convection is the heat-transfer mechanism on the liquid side. This initiates vaporization at the surface with only slight superheating of the liquid. Therefore, the laws governing heat transfer by free convection apply. At higher temperature differences, nucleate boiling begins. For both boiling regimes, the film heat-transfer coefficient α_L depends on the temperature difference ϑ_L and is characterized by the relationship:

$$\alpha_L = C \cdot \vartheta_L^n \tag{56}$$

In the free convection regime, $n = 0.33$. For nucleate boiling, the value of n is in the range 2 – 5. The liquid film heat-transfer coefficients for submerged tube evaporators, however, are not as favorable as, for example, for circulating vaporizers with vertical tubes. Figure 15 shows this comparison.

Figure 15. Heat-transfer coefficient in recirculating and submerged tube evaporators

In addition to the construction shown in Figure 11 D, horizontal heat exchangers having two tube sheets are also in use. This style of evaporator also finds application as a trickle film vaporizer, for example, for seawater desalting or in the refrigeration industry. In these, there is a liquid sump underneath the tube bundle. A pump removes solution from the sump and conveys it to a device that distributes it over the outer surface of the tube bundle. Here it vaporizes from a thin liquid film. This principle of operation totally avoids the disadvantage of any elevation of the boiling point by liquid static pressure. Beyond that, is the advantage that the liquid inventory required for operating the evaporator is comparatively small.

Additionally, related also to a low liquid inventory, the residence time of the feed material in the unit can be a deciding factor in the choice of evaporator type. Many evaporating solutions incline toward undesirable chemical or physical changes if they are exposed too long to temperatures too high. To be able to vaporize even such solutions gently requires evaporators having low residence time for the evaporating material. At present, with the normal recirculating evaporators, to achieve the desired concentration the liquid undergoes repeated recycling through the equipment. Moreover, it is exposed to the evaporating temperature for a comparatively long time. Thus, for concentrating thermally unstable solutions, a type of evaporator permitting more gentle treatment of the solution should be installed: that is, one in which the liquid reaches its specified final concentration after only one pass through the vaporizer tubes. Designs are available in which the product stream flows not only from bottom to top, Figure 11 E, but also from top to bottom, Figure 11 F. If the space available does not permit the required height, then, in any case, the desired final concentration may be attained by linking several units together in series each having shorter vaporizing tubes.

For units with upward product flow, if the superficial velocities (based on the inside cross-sectional area of a tube of diameter d_i) not only of the liquid phase, index L, but also of the vapor phase formed by boiling, index V, are known, the film heat-transfer coefficient for liquid boiling may be calculated by a relation developed by COULSON and MCNERLY:

$$\alpha_L = \frac{1.3 + 128 d_i}{d_i} \cdot \lambda_L \cdot \left(\frac{c_L \eta_L \varrho_L}{\lambda_L}\right)^{0.9} \cdot \left(\frac{u_V d_i \varrho_V}{\eta_V}\right)^{0.34} \cdot \left(\frac{u_L d_i \varrho_L}{\eta_L}\right)^{0.23} \cdot \left(\frac{\varrho_L}{\varrho_V}\right)^{0.25} \frac{\eta_V}{\eta_L} \tag{57}$$

A principal field for once-through evaporators is the concentration of solutions of alkalis and

Figure 16. Heat-transfer coefficient for surface evaporation of refrigerant R11 in a falling film

Figure 17. Heat-transfer coefficient for a falling film evaporator as a function of the feed rate
v = feed evaporated, % and ϑ = temperature difference between the steam and the boiling liquid

salts: NaOH, KOH, Na_2S, and $CaCl_2$. In these applications, frequently, two-stages systems are installed with total utilization of the solvent vapors. The first stage is a once-through vaporizer, preconcentrating the solution from about 50 – 75 % by weight salts, while the main thickening to 99 % solids takes place in a falling film evaporator.

The evaporating liquid flows downward in a falling film evaporator. Liquid, usually preheated, enters the unit above the upper tubesheet. Suitable devices distribute the liquid uniformly among the outside heated evaporator tubes. The liquid then flows downward with partial vaporization as a thin film on the inner tube walls. The momentum of the likewise downward flowing evaporated vapors assists in accelerating liquid downflow, reducing liquid film thickness. This means of operation results in a substantially lesser liquid residence time even than that

for the once-through vaporizer. In single-stage systems, the residence time is less than a minute, in comparison to the recirculating evaporators, an advantage in evaporating heat-sensitive solutions.

In determining the film heat-transfer coefficients on the liquid side of falling film evaporators, the physical laws valid for trickling films are valid if conservative. In so doing, the purely laminar region, the pseudo laminar or wavy laminar region, the transition region, and, finally, the turbulent region are differentiated. In these differing regions, heat-transfer phenomena obey different laws for the trickling film since the average film thickness, the film configuration, and the discharge velocity are different. The measured results shown in Figure 16 illustrate this. The data apply to vaporizing a trickling film of refrigerant R11 on a clean surface with fully developed flow. Figure 16 shows the dependence of the film heat-transfer coefficient of the vaporizing, trickling film α_L on the specific liquid loading l (kg m^{-1} h^{-1}) or l' (m^3 m^{-1} h^{-1}), the amount of liquid that flows down 1 m of tube circumference in 1 h. Since the principal liquid side heat-transfer resistance itself lies in the trickling film (for purely laminar flow, the region on the left of Figure 16) Equation (58) permits determination of α_L:

$$\alpha_L = \frac{\Delta h \varrho_L^2}{3\eta_L \vartheta_L H}\left(s_0^3 - s_u^3\right) \tag{58}$$

The film thickness, so at the feed entry position, i.e., the upper end of the tube, for laminar film velocity distribution, is given by the Hagen – Poiseuille law when the quantity of liquid feed L_o(kg/h) fed to each evaporator tube with inside diameter d_i is known:

$$s_0 = \sqrt[3]{\frac{3\eta_L L_0}{\varrho_L^2 \pi d_i 3600}} = \sqrt[3]{\frac{3\eta_L l_0}{\varrho^2 \cdot 3600}} \tag{59}$$

Equation (60) allows calculation of the film thickness s_u at the lower end of the tube with length H(m), i.e., at the outlet position:

$$s_u = \sqrt[4]{s_D^4 - \frac{4\lambda_L \eta_L \vartheta_L H}{\Delta h \varrho_L^2}} \tag{60}$$

In Equations (58) – (60), the liquid-film material properties are taken at the average temperature of the trickling film, taking into account the temperature drop ϑ_L between the tube inner wall and the surface of the film.

Figure 18. Falling film evaporator with circulating pump

An important prerequisite for smooth operation of a falling film evaporator and for effective heat transfer is complete wetting of the heating surface. This means that, in design, the specific liquid loading l'_0 (m^3 h^{-1} m^{-1} = m^2/h) must be chosen with care so that it is not too small. To achieve sufficiently high film heat-transfer coefficients, Figure 17 shows that the specific feed quantity at the upper end of the tube l'_0 should be:

$$l'_0 > 1.0 - 1.5\,\mathrm{m^3 h^{-1} m^{-1}} = \mathrm{m^2 h^{-1}} \tag{61}$$

In industrial systems, in special cases, dealing with evaporative degassing, for example, smaller liquid loading values are chosen as well, as low as $l'_0 = 0.3$. But otherwise, l'_0 values frequently lie above 2 m^3 h^{-1} m^{-1}.

Using a recycle pump for recycling liquid to achieve complete tube surface wetting is common, for example, for falling film evaporators in the edible oils industry. Figure 18 shows a scheme for thermally separating free fatty acids

from nonvolatile residue. Since such systems operate at high vacuum, less than 1 kPa, one must take care in design that the vapors developed do not cause an inadmissably high pressure drop. By dividing the heat-exchange surface into more than one bundle and removing the device for separated vapor withdrawal from the exchangers, the vapor hydraulic losses can be held correspondingly low.

Figure 19. Falling film evaporator with partial countercurrent and partial cocurrent flow of liquid and vapor

In principle, it is also possible to design units in which vapor and liquid flow partially cocurrently and partially countercurrently to one another, as in Figure 19. By varying the number of tubes in the respective separate exchanger bundles or changing the tube diameter along the direction of liquid flow, the specific liquid loading on the tube circumference l'_0 can be maintained high enough that the system can operate without a recycle pump. This design has proven to be advantageous as the final stage in fatty acid evaporation systems.

Table 3 lists parametes, including heat-transfer coefficients, for some falling film evaporators from operating industrial systems.

Relatively small temperature differences between heating medium and evaporating liquid, as little as 4 °C, are possible in operating falling film evaporators. Moreover, the design excludes superheating the liquid due to static liquid head. Thus, at a given operating pressure, the boiling temperature is lower than in conventional evaporators. At a liquid viscosity of about 1 kg/ms, the lower limit of pressure is an operating vacuum of about 4 kPa.

Figure 20. Wiper systems for thin film evaporators

Figure 11 G illustrates a thin film evaporator with rotating internal element. These are suited for heat-sensitive products requiring low evaporator operating pressures, down to 0.1 kPa, and having liquid viscosities far above 1 Pa s. Mechanical wipers rotate inside an externally heated cylindrical shell, as shown schematically in Figure 20. They produce sufficiently intensive agitation to develop thin films even with high viscosity liquids. The film thickness varies in the range 0.5 – 2 mm depending on the design and the speed of rotation. The product residence

Table 3. Coefficient of heat transfer for some industrial applications of falling film evaporators

Falling film evaporator	Styrene distillation	Fatty acid distillation	Fatty acid fractionation
Tube dimensions, mm *	38.1×2.64×3000	76.1×2.9×3000	76.1×2.9×3000

* inner diameter (d_i) × wall thickness (s_w) × height (H)

time, depending on the loading conditions, may be even less than that for falling film evaporators.

The liquid to be vaporized enters the unit above the heated wall and distributes uniformly around the circumference. The wiper system provides for developing a thin liquid film which flows downward along the hot wall under the influence of gravity while evaporating to a higher concentration. Designs using self-aligning, pendulum wiper systems and those using sliding guide shoes have potential for thickening solutions of solids to the point that the end product leaves the evaporator in powder form.

Inherent in the design concept is that these evaporators must operate with a comparatively large temperature difference. Now, since the thin films produced by the rotating wiper systems result in residence times less than 1 min for the material being concentrated, substantially higher temperatures may be used in evaporating solutions of temperature-sensitive substances than, for example, with circulating vaporizers.

Equation (62), a result of the experimental investigations of DIETER, permits calculating approximate values of the film heat-transfer coefficients α_L for thin-film evaporators with rotating internal elements:

$$\alpha_L = K \cdot \sqrt[3]{d_i \cdot n_r} \cdot \frac{\lambda_L}{\eta_L^{1/3}} \tag{62}$$

The nomenclature for Equations (62) – (64) is as follows:

K = a constant with the numerical value 500
d_i(mm) = internal diameter of the heating cylinder wall
n_r(min^{-1}) = rotor rotational frequency
λ_L($W\ m^{-1}\ K^{-1}$) = thermal conductivity of the liquid film
η_L($kg\ m^{-1}\ s^{-1}$) = dynamic viscosity of the liquid film
u_w(m/s) = wiper circumferential speed
d_w(m) = wiper diameter
f_w(s^{-1}) = wiper frequency
H (m) = length of the heated cylinder wall
D (kg/h) = evaporator capacity in terms of solvent evaporated
d ($kg\ m^{-2}\ h^{-1}$) = specific evaporator capacity

Equation (63) gives the rotor rotational frequency given the wiper circumferential speed:

$$\eta_r = \frac{60}{\pi} \cdot \frac{u_w}{d_w} \tag{63}$$

Recommended values for u_w are 8 – 9 m/s for fixed and 3.5 – 4 m/s for movable wipers. For thin film evaporators of industrial size, wiper frequencies f_w from 15 to 20 have shown favorable operating experience. Then, the wiper frequency results from u_w, f_w, and the wiper diameter d_w.

Figure 21 makes it possible to estimate the expected heat-transfer coefficients for some uses of industrial interest. Equation (64) defines the specific evaporator capacity d. Equation (65) shows the relationship between d, the average heat transfer coefficient k, and the assigned total temperature difference between the heating medium and the vaporizing liquid ϑ. Given the solvent latent heat of vaporization Δh and temperature difference ϑ sets the specific evaporator capacity d:

$$d = \frac{D}{d_i \pi H} \tag{64}$$

$$d = k \cdot \frac{\vartheta}{\Delta h} \tag{65}$$

Thin film evaporators with rotating internal elements are especially suited for temperature-sensitive materials that decompose easily or change chemically during evaporation in conventional equipment. Condensation and polymerization are among possible chemical

changes. Applications include concentrating substances whose taste and active ingredients are not permitted to degrade. Vaporizing fatty acids or softeners, for example, requires low vacuum on the product side and high temperature on the heating medium side. For such cases, the heating medium often is Dowtherm, an azeotropic mixture of diphenyl and diphenyl oxide, or HT-OIL-C. Further fields of application are concentration of fruit juices, milk, yeast, pectin solutions, dyestuff solutions, gelatin solutions, glues, gums, plant extracts, recovery of drug extracts and serums, distilling solutions of organic solvents or mixtures of such with water, and partial separation of multicomponent mixtures.

However, based on industrial experience, it is known that thin film evaporators with rotating wipers are not successful in all cases for all thermally unstable materials. The reason is that even product residence times of one minute are too long. If product residence times of only one second are required for liquids of high viscosity, 20 kg/ms and more, for example, then conventional evaporators are not applicable or acceptable only with limitations on product yield and quality. A completely different design concept (Fig. 11 H) enables successful solution of even these vaporizing problems. The advantage inherent in this design is extremely mild vaporizing behavior. For example, the residence time in the actual vaporizing zone on the heat-transfer surface may even amount to only fractions of a second.

In this equipment, as in many designs of molecular distillation apparatus, the vaporizing surface rotates. Under the influence of high centrifugal forces resulting from correspondingly high rotational frequency, the liquid spreads out in an extremely thin film moving at high velocity. Varying the feed rate and the rotor rotational frequency up to 1600 revolutions per minute permits stepfree adjustment of the film thickness within defined limits. On the average, under normal operating conditions, even with comparatively viscous liquids, the film thickness amounts to only ca. 0.1 mm. With rotational speed adjusted to feed rate conditions and liquid viscosity, the film thickness can successfully be held low in such equipment, even at relatively high liquid rates. This leads to comparatively high radial film velocities and to relatively high heat-transfer coefficients at the particular position considered on the vaporizer rotor at the varying cone diameter d_k.

In addition, this principle of operation also creates favorable conditions for heat transfer on the heating medium side of the vaporizer unit. If steam is that heating medium, then it condenses predominantly in the form of droplets whose size decreases with increasing rotational frequency. Now, since centrifugal force flings the condensate drops off the condensing surface immediately after they are formed, the heat-transfer resistance is substantially less than in conventional condensing systems. Consequently, the heat-transer coefficients on the condensing steam side are about an order of magnitude higher than for pure film condensation of the heating steam.

Operating thin film vaporizers having the design concept shown in Figure 11 H best fulfills the prerequisites for good heat transfer on both sides of the heat-transfer wall of the vaporizer unit. Heat-transfer coefficients k are a factor of about two to four times higher, depending on the thermal conductivity resistance of the vaporizer wall, than, for example, those for conventional falling film vaporizers. This results in less heating surface or even using a comparatively small temperature difference between heating medium and product and thus a lesser wall temperature on the product side. The high realizable heat transfer coefficients result in high specific evaporating capacity and thus comparatively small equipment volume.

The heat-transfer coefficients vary over a broad range in accordance with the vaporizer-rotor frequency, the physical property values of the feed material at the operating conditions, as well as the state of the heating medium, heating surface loading, and capacity. Numerical values for k range between 500 and 10 000 W m^{-2} K^{-1}. Total temperature differences ϑ may lie between 5 and 80 °C. Whereas the high heat-transfer coefficients given in Table 4 are more typical of dilute solutions, heat-transfer coefficients calculated for vaporizing liquids with high solids concentration would be an order of magnitude lower. But even for such evaporation problems, the figures given in Table 5 show the unmistakable advantages of the vaporizer with rotating heating surface, attesting convincingly to its far superior heat-transfer performance.

Figure 21. Heat-transfer coefficients for thin film evaporators for some applications as a function of the specific evaporator

t_{WL}, °C	130.4	103.8

Installation of a thin film evaporator with rotating heating surface is advantageous in all cases for applications which require, in operation, the lowest possible wall temperature on the product side. It is a relatively versatile device finding application in the chemical and pharmaceutical industries, the edible oil industry, and not the least in the foodstuff industry, for small to medium capacities.

At fixed operating conditions, the transfer-rate coefficient k and the difference between the temperature of the heating medium t_H and the boiling temperature $(t+\tau)$ set the size of the heat-transfer surface A of the evaporator heating element for the heat-transfer duty Q through the equation:

$$A = \frac{Q}{k\,\{t_H - (t+\tau)\}} \tag{66}$$

Correspondingly, Equation (67) determines the size of the required heat-transfer surface for a given evaporator stage of a multistage system, where Q_n is the stage duty. The temperature difference $\{t_{n-1} - (t_n + \tau_n)\}$ refers to the difference between the solvent saturation temperature corresponding to the pressure in the previous stage and the boiling temperature in the stage under consideration:

$$A_n = \frac{Q_n}{k_n \{t_{n-1} - (t_n + \tau_n)\}} \tag{67}$$

Figure 22. Arrangement of the vapor separation chamber in various types of evaporators

4.2. The Vapor Separation Chamber

The vapor separation chamber, or vapor head, has the job of separating the two phase, vapor – liquid mixture that flows into it from the evaporator heater element into its components. The separated vapor should be free of entrained liquid particles. This will, insofar as is possible, prevent fouling the condensing surface of the vapor condenser in single-stage systems or of the vaporizing surface of the succeeding stage in mul-tistage systems. For its part, the liquid leaving the vapor separation chamber should be as completely free of vapor as is possible.

The orientation of the vapor separation head relative to the evaporator heating element, its design features, and the way in which the vapor – liquid mixture is introduced, determine the degree to which the unit will fulfill the aforementioned requirements. Thus, among the basic conceptual evaporator designs shown in Figure 11, there are merely three principal vapor separation head configuration variations. Figure 22 illustrates these.

The arrangement in Figure 22 A refers to submerged tube vaporizers called kettles or for simple evaporator drums heated through the walls. In these constructions, the vaporizing element and the vapor separation chamber form a single unit. The design in Figure 22 B illustrates the vapor separation chamber arrangement corresponding to the Robert or calandria evaporator, recirculating evaporators with external liquid downcomers, as well as to once-through vaporizers. In these, the vapor – liquid mixture enters the vapor separation head from below, directly under a pool of accumulated liquid. Finally, the design in Figure 22 C shows the configuration for all recirculating evaporators with externally arranged heat exchanger elements, falling film evaporators with vapor separation chamber below the exchanger, as well as vaporizers flashing preheated solutions. This last arrangement has the feature that the vapor – liquid mixture enters the vapor head above the pool of accumulated liquid. This allows the level of accumulated liquid to be set comparatively low.

Thin film evaporators with rotating internal elements, in general, have no vapor separation chamber in the same sense as the designs shown in Figures 22 A, B, and C. However, they do possess special internal devices for removing entrained liquid droplets from the vapor.

The vapor separation head is so dimensioned that liquid contained in the separated vapor phase is limited to just the minimum physically attainable. This is in the form of small, entrained liquid particles corresponding in size to equilibrium among the gravity, inertial, surface tension, viscous, and drag forces extant. Installing liquid separators as illustrated in Figure 23 achieve further purification of the exiting vapor from residual liquid. Setting the dimensions of the vapor separation chamber determines the specific vapor volume per hour per cubic meter of

chamber volume that a given head can handle at the least liquid content. Empirical Equations (68) – (70) serve to calculate this flow of vapor v in accord with the three characteristic vapor separation chamber configurations A, B, and C of Figure 22. These apply to a vapor separation head pressure of 100 kPa.

Equation (68) applies to the case shown in Figure 22 A where H_v (m) is the height of the vapor space measured from the liquid surface to the demister pad or droplet separator. The most favorable vapor separation capacity v_a ($m^3\ m^{-3}\ h^{-1} = h^{-1}$) is:

$$v_a = 500 + \frac{40}{0.01 + (H_V)^{3/2}} \tag{68}$$

Extending Equation (68) gives Equation (69) applying to Case B where H_w (m) is the height of the accumulated liquid level in the vapor head and H_v and v_a are as above. Then the most favorable vapor separation capacity v_b ($m^3\ m^{-3}\ h^{-1} = h^{-1}$) is:

$$v_b = v_a + \frac{1}{(1 + 1.1 \cdot H_W)^4}\,(4500 - v_a) \tag{69}$$

For Case C, the most favorable vapor separation capacity v_c ($m^3\ m^{-3}\ h^{-1} = h^{-1}$) is constant:

$$(v_c)_{H_v > H'_v} = 7300 \tag{70}$$

For operating pressures different from 100 kPa, Equation (71), with the help of Equations (68) – (70) and the pressure factor f read from Figure 24, permits converting the most favorable vapor separation capacities v_a, v_b, and v_c to the revised pressure basis:

$$(v_{a,b,c}) = f \cdot (v_{a,b,c})_{p=1} \tag{71}$$

For a given hourly evaporated vapor flow D (kg/h) with density ϱ_D (kg/m^3), Equation (72) determines the required height of the vapor separation head H_v, where H_v is the distance measured from the liquid surface to the demister pad or droplet separator for removing entrained liquid particles from the vapor stream:

$$H_V = \frac{1}{d_B^2 \pi / 4} \cdot \frac{D}{\varrho_D\,(v_{a,b,c})_p} \tag{72}$$

For the vapor separation chamber-free crosssectional area and water vapor at atmospheric pressure, allowable vapor velocities u_D of 1 m/s are the usual in practice. At lower pressure, the equations give even higher vapor velocities. Then Equation (73) sets the diameter d_B of the vapor separation chamber:

$$d_B = \sqrt{\frac{4D}{\pi u_D \varrho_D \cdot 3600}} \tag{73}$$

Since the liquid density is practically independent of pressure, geometrically similar vapor separation heads are then about equal in their separation effect when operating at equal velocity head. When the pressure differs from 100 kPa, the following relationship applies for setting the vapor velocities u_D in the vapor separation chamber:

$$(u_D^2 \cdot \varrho_D)_{p_1} = (u_D^2 \cdot \varrho_D)_{p_2} = (u_D^2 \cdot \varrho_D)_{p_n} \tag{74}$$

Operation of industrial evaporator systems shows that, even at comparatively low vapor velocities in the vapor separation chamber, some liquid is always entrained by the flowing vapor if no special measures are taken for their separation. Even using liquid separators, it is not always possible to remove the smallest liquid droplets. In general, relying on the force of gravity alone achieves a separation effect up to 70 %.

Figure 24. Pressure factor f for Equation (71)

The stability of the liquid drops is a determining factor in designing liquid separators. The We-ber number is the principal criterion for drop

Figure 23. Liquid separators

stability. The Weber number is equal to the quotient of the velocity head arising from the vapor flow external to the drop p_s and the internal excess pressure of the drop p_u caused by the surface tension along the phase boundary between the drop and vapor. In designing liquid separating devices, the critical Weber number of 22 should not be exceeded so that the larger drops do not break up. From this condition, the relationship expressed by Equation (75) results for the highest allowable velocity in the separator. This equation shows the dependence of the highest allowable velocity in the separator on the surface tension of the liquid σ (kg/m), the vapor density ϱ_D (kg/m^3), and the diameter d_T (m), of a liquid droplet.

$$(u_D)_{max} = 4.7\sqrt{\frac{\sigma}{\varrho_D \cdot d_T}} \tag{75}$$

In industrial evaporator systems, the desired degree of purity of the vapors determines the type of separator device. For the most part, separators use reversal of the vapor flow and liquid flow or both to create impingement force or the many varieties of centrifugal force for liquid drop separation. The designs used in practice, then, range from simple baffle and reversing plates to cyclone type internals as well as packed beds and demister pads in the vapor separation chambers. Figure 23 shows a sampling of design concepts. A simple baffle plate suffices as a liquid separator if a vapor flow no more than 1000 – 2000 m^3/h escapes from each square meter of liquid surface in the vapor separation drum.

Consequently, in the free space of a vapor separation drum, predominantly the gravity force determines the effectiveness of separation of the liquid particles entrained by the vapor. With an internally installed separator device, impingement or centrifugal force or both are controlling. Therefore, the degree of separation depends on the extent to which use of these mechanical forces permits smaller drops to coalesce into larger ones. It is self-evident that physical properties like large density difference between the phases and high surface tension of the separated liquid exert a favorable influence. Then for any separator a minimum limiting drop size exists such that drops of smaller size will no longer be separated.

Beds of packing are low-pressure drop devices especially well suited for separation of liquid drops measuring down to about 300 µm. For ring or saddle-shaped packings, the preferred sizes to use are those with principal dimension 15 – 25 mm. Because of their relatively thin wall thickness, use of metal packings results in a lesser pressure drop than that for those manufactured from ceramic materials. Supported on expanded metal mesh, these packings should form a bed of ca. 200 – 300 mm height across the total vapor head cross-sectional area under the vapor head cover.

If very small liquid droplets must be removed from the vapor stream, the recommended device to install is a demister pad, comparatively tightly woven wire mesh packings. At vapor velocities 2 – 5 m/s, they can separate drops down to 3 µm in diameter. Moreover, for these materials, the pressure drop amounts to 15 – 40 mm water column per meter of packed height. Such demisters make possible almost 100 % removal of liquid.

5. Evaporator System Ancillary Components

A number of additional engineered instrument or equipment items are necessary for operating an evaporator system. Thus, in most cases, fresh feed solution requires preheating in a heat exchanger. These are heated either with evaporated vapors, the hot concentrated product, or steam condensate from the evaporator heating element. Not uncommonly, it is also necessary to degas the fresh feed solution before it enters the evaporator to avoid corrosion. Frequently, it may also be necessary to free the concentrated product from the evaporator of residual solvent components with a degassing step. Additionally, pumps are required for feeding the systems, to produce recirculating flow, for product disposition, as well as for producing vacuum. Finally, it is necessary to control the total system, consisting of evaporators and auxiliary equipment, to ensure an automatic and essentially upset-free, safe operation.

5.1. Indirect Heat Exchangers

Preheating, cooling, condensing, and degassing require installing heat-exchange equipment. These may employ direct or indirect heat transfer as their principle of operation. In the indirect method, the streams involved are sepa-rated from one another by a wall through which the heat flows as a result of the difference in temperature. The direct method brings the streams into intimate contact. Normally, most equipment for feed preheating or product cooling employs the method of indirect heat transfer. For preheaters heated by evaporated vapors as well as by product concentrate and condensate cooling, units built as tubular exchanger bundles are usually preferred. Depending on the operating conditions and location factors, one may select either a vertical or horizontal arrangement of the tubes. Inclined tube arrangement applications remain limited to rare cases only.

Surface condensers for evaporated vapors have an important position among heat exchangers using indirect heat transfer. Insofar as vapor generated in single-stage evaporator equipment is not used for preheating or degassing the fresh feed solution, it is condensed in a condenser. Likewise, if the condensation heat of vapors from the last stage of a multistage evaporator is not utilized in some other manner, then they must be condensed in a condenser. The same applies to the so-called residual vapors from vapor recompression evaporators.

The first objective of vapor condensors is to maintain the boiling pressure required in the evaporator stage by continuously condensing the vapors developed and removing the noncondensable gases. Therefore, since often pressures must be held lower than one atmosphere, the methods named are the simplest and most economic to produce the desired lower pressures. To the extent that the condenser operates in the negative pressure domain, the vacuum pump connected downstream serves to remove leakage air or other noncondensable gases. If the main purpose of the evaporation is recovery of the evaporated solvent when it is a valuable product, or to recover the evaporated solvent in the pure form, then condensing the vapors in a surface condenser is the optimum industrial solution. This applies to that vapor not condensed in the heating elements of the stages heated by evaporated vapors in multistage evaporator systems.

5.2. Equipment for Direct Heat Exchange

Heat exchangers in which tube walls separate the streams being cooled from the streams being heated are not always the optimum conceptual solution to a heat-transfer problem. If the substances taking part in the heat transfer are permitted to come in contact with one another, then it may be possible to install equipment for heat transfer directly between them. These units may be less expensive than tubular heat exchangers. The so-called barometric condensers for condensing vapor by direct heat exchange between vapors and cooling medium belong to this field of evaporator design; likewise, the direct degassing equipment for removing gases dissolved in the fresh feed solution to be evaporated. If not degassed, corrosion or impairment in heat transfer could then result in the evaporator. Lastly, the units for degassing the product concentrate from the last evaporator stage by direct contact steam stripping are also in this group.

Comparatively low installed cost distinguishes the barometric condensers using cooling water to condense vapors in industrial systems for evaporating aqueous solutions. The flow direction of the two media differentiates cocurrent (Fig. 25) from countercurrent (Fig. 26) barometric condensers. Based on economic considerations, the latter are most frequently used.

Figure 25. Cocurrent flow barometric condenser

In barometric condensers, a direct heat exchange takes place between vapor and cooling medium through intimate mixing of both materials. In barometric condensers operating countercurrently, the vapors D to be condensed with the enthalpy h enter the condenser at the bottom. Of necessity, they rise countercurrent to the cooling water W flowing from above. The condensed vapor leaves the unit together with the cooling water through the barometric leg. The cooling water temperature rises from the inlet value t_{W} to the common end temperature t_{K}. In general, the vapors entering the condenser contain noncondensable gases G. Especially when operating under vacuum, this gas consists predominantly of air leakage. But, in addition, depending on the nature of the solution to be evaporated, this gas may also contain small quantities of carbon dioxide or ammonia, for example. In the condenser, these gas flows are cooled from their inlet temperature, equal to the vapor temperature t to the final temperature t_{G}. A vacuum pump removes the noncondensable gases after separation of still entrained liquid droplets by a liquid separator located immediately downstream of the condensing chamber.

Figure 26. Countercurrent flow barometric condenser

Through direct heat exchange, under otherwise the same conditions, using a barometric condenser permits achieving a usefully lower pressure than with a surface condenser. Equation (76) gives the required cooling water flow for a countercurrent barometric condenser:

$$W = \frac{D\,(h_{\mathrm{D}} - h_{\mathrm{K}}) + G c_{\mathrm{G}}\,(t - t_{\mathrm{G}})}{h_{\mathrm{K}} - h_{\mathrm{W}}} \tag{76}$$

In Equation (76), c_{G} (J kg^{-1} K^{-1}) represents the specific heat of the gas, and h_{W} or h_{K} (J/kg) are the enthalpies of the cooling water and of the condensate. In this balance, heat losses are neglected.

The cooling water consumption necessary for the required condensing capacity depends critically on the temperature level of the exit cooling water – condensate mixture. A high exit water temperature t_{K} results in lower cooling water consumption. On the other hand, the noncondensable gas outlet temperature t_{G} also in-

creases with an increasing value of t_K leading to an increase in the suction volume to the vacuum pump. One may estimate the value of t_G from the empirical equation:

$$t_G = t_W + 4 + 0.1\,(t_K - t_W) \tag{77}$$

In practice, with countercurrent barometric condensers, an exit water temperature t_K that is 6 – 8 °C less than the vapor temperature at the condenser inlet has proven economical.

A barometric condenser must be designed so that it achieves total vapor condensation. This requires a correspondingly large contact surface area between the vapor and cooling water and a sufficiently long residence time in the equipment. Obtaining sufficient contact surface between evaporated vapors and cooling water is a matter of installing internal devices in the usually cylindrically shaped condensation chambers. Suited for this, aside from packings, are also contact trays as well as disc-and-doughnut baffles or shower decks. Moreover, in addition, designs are conceivable which spray the cooling water into the condensing chamber through atomizing nozzles to produce sufficiently high contact surface.

With countercurrent barometric condensers, if available equipment layout space permits sufficient elevation of the condensation system, the mixture of cooling water and vapor condensate leaves the condensing chamber through a simple pipe downcomer or barometric leg. This simple construction concept makes the condensate pump otherwise required, unnecessary or simplifies its design, control, or operation. In sizing the barometric leg, the water column existing in the leg must compensate for the negative pressure in the condensing chamber, in accordance with the principles governing ducts connecting to the surrounding atmospheric pressure. The minimum height of this water column H_{min} (m) is given by the following equation:

$$H_{min} \simeq \frac{p_u - p}{\varrho_W} \cdot 10^4 \tag{78}$$

In Equation (78), p_u (Pa) represents the ambient pressure, p (Pa) the negative pressure prevailing in the condenser, and ϱ_W the density of water, which, as a practical matter, may be set equal to 1000 kg/m^3. At a flow velocity of ca. 1 m/s, an additional liquid head of a maximum of ca. 0.8 m must be added to this minimum water column height. This takes into account the pressure drop arising from the cooling water and condensate flow in the downcomer. The total height of the liquid column thus determined, $H = H_{min} + 0.8$ (m), ensures positive removal of cooling water and condensate. Simultaneously, it maintains the operating pressure in the condenser.

The barometric leg empties into a receiver installed under it. The receiver must be so sized that its capacity for liquid, beyond that for discharge from the leg, is at least 1.5 times the volume of the leg.

Figure 27. Liquid degasser

Degassing of liquids plays an important part in engineering evaporator systems. Liquids have the tendency to dissolve gases, for example, air, carbon dioxide, ammonia, oxygen and the like, in small quantities. Then, when the liquid warms to the boiling point, the gases are almost completely eliminated. If they are not removed in a timely manner, they may concentrate in the system and cause problems, e.g., deterioration in

heat transfer in steam heated equipment, or perhaps corrosion, or may damage the product by oxidation. Thus, degassing enjoys a special significance, not only for the fresh feed solution, but also, in many cases, for the intermediate or end products. In general, degassing is accomplished through direct heating with evaporated vapor. This warms the liquid practically to the boiling point prior to vaporization. The degassing pressure may be chosen to be the same as that of the first evaporation stage, but lower pressures may also be desirable. Ordinary degasser designs are conceptually similar to countercurrent barometric condensers. The liquid to be degassed flows countercurrent to steam or evaporated vapors entering from below for heating.

Figure 27 shows a compact assembly of liquid degasser integrated with an evaporator. This degasser design uses packing to achieve the required contact surface between liquid and vapor. Other designs employ shower decks or the well-known trays used in distillation or a combination of both.

Degassing a liquid or solution is thus synonymous, in the process engineering sense, with directly preheating it with steam or vapors almost to its boiling point. This direct condensation of steam or vapors results in mixing the condensate formed with the liquid being degassed. Then, in general, these degassing methods may be used only when dealing with the same kind of materials for both vapors and liquids. This is the case when the fresh feed solution is degassed by direct preheating with vapors produced from its own evaporated solvent. Degassing of liquids may be required for reasons of maintaining or improving product quality. Figure 28 is a sketch of an equipment arrangement applied, among others, with success in industrial installations for such cases. This example schematically shows combined degassing, dewatering, and deodorizing fatty acids in a falling film degasser. The key equipment item in the system is an externally heated falling film vaporizer charged at the bottom with stripping steam. Preheated raw acid enters the upper section. It then flows downward as a thin film on the inner walls of the vaporizer tubes countercurrent to the stripping steam, thus not only degassed but also dewatered and deodorized. By previously removing the oxygen in the upper portion of the vaporizer tubes, no damage to the product occurs by oxidation in the lower portion even above 175 °C. The purified fatty acid exits from the bottom of the unit. The condensate dropping out in the condenser flows to a downstream separator. There it separates into a heavy aqueous phase and a small quantity of light fatty acid phase enriched in the color and odor carriers.

5.3. Pumps

In designing evaporator systems, special care must be given to the selection, arrangement, and operation of pumps for transferring liquids and for producing vacuum. Pumps recycle the liquid in forced circulation evaporators. Suitable pumps withdraw the concentrated product from the evaporator system. The vacuum pump unit must operate at the highest level of reliability as pumps withdraw the concentrated product from an indispensable condition for ensuring freedom from upsets in vacuum evaporator system operation.

Pumping capacity, materials of construction, and principle of operation are determining factors in pump selection. Pumps normally available on the market can fulfill the requirements for the preponderant number of applications. In special circumstances, for example, for oxygen-sensitive products in vacuum operations, only pumps without seals and having submerged electric motors, so-called “canned pumps”, or pumps equipped with magnetic couplings, suffice.

Evaporator systems operating under partial or full vacuum, with pressure in the condenser under one bar (0.1 MPa) require a vacuum unit. This removes the noncondensable gases which, in most cases, consist predominantly of air, from the condensing chamber. In general, this unit connects directly to the evaporated vapor condenser. Aside from mechanically operating vacuum pumps, steam jet vacuum pump installations have also proven successful. In their principles of construction and method of operation, these are comparable to steam jet compressors. A single jet is able to produce only a limited compression ratio. To obtain higher vacuums requires connecting several jets in series with one another. A single jet can reach a vacuum of about 10 kPa absolute pressure; two jets can attain about 4 kPa; and three down to 1.3 kPa.

Figure 28. Degassing fatty acids in a falling film evaporator

A high steam consumption results if the vapors compressed in a jet stage of a multistage system pass on to the succeeding jet. To avoid this, intercondensers are installed between the jets to condense the vapors as well as the motive steam. Figure 29 schematically shows this mode of operation.

5.4. Control Instrumentation

Control and surveillance enables determining acceptable values of the characteristic process and operating variables. The multitude of process variants, as well as the variations in operating conditions and desired product purities, do not permit a generally valid standard control concept applicable for all or any evaporation processes. Rather, for best control of a particular evaporator system, a new control concept is developed for that application.

As an example, in multistage recirculating evaporator systems, controllers for the liquid level in the vapor separation chambers, in reality, control the liquid flow through all units by means of throttle valves in the feed liquid piping to each stage. Figure 30 shows this concept. A call for a change in level in any given stage propagates through the upstream stages.

In principle, the evaporating vapor temperature in the last stage of a multistage evaporator system is the control variable regulating the heating steam flow to the first stage. In the concept shown in Figure 30, holding constant pressure in the last stage vapor separation chamber permits using the temperature difference between heating steam and last stage vapors as the control variable.

A density measurement loop in the product drawoff can be used to achieve uniformity of the product concentrate. A controller picking up

Figure 29. Multistage steam jet vacuum pump

Figure 30. Throughput control in a multistage evaporator system
ISO codes: LIC, level indicating controlling; PIC, pressure indicating controlling; TdIC, temperature difference indicating controlling

this signal can adjust a three-way valve located downstream of the product drawoff pump. Then, deviations from the setpoint density change a partial product recycle flow back to the last evaporator stage. This makes it possible to achieve a correction in the product concentration. In this case, the level controllers serve to readjust the operation of the upstream evaporator stages.

5.5. Insulation

Well-conceived and maintained insulation on vaporizer equipment and piping in an evaporator system serves to reduce local heat losses extensively. This prevents partial refluxing of the evaporated vapors, and rather beyond that, especially avoids overloading the evaporator heating element also.

The insulation normally used depend for their effectiveness on their extremely low thermal conductivity. Low thermal conductivity follows from their low bulk density, characteristic of their porous or wooly nature.

An optimum insulation thickness is usually determined. For this, the annual costs of both the insulation and the expense resulting as a consequence of the heat losses are needed. The annual

cost of insulation is the depreciation. Both costs depend on the insulation thickness. When the sum of the annual costs is plotted versus the insulation thickness, the minimum cost represents the optimum thickness. Determining the optimum insulation thickness is an especially important task in design of evaporation systems with open-air construction, frequently the case in chemical plants. During the winter months, heat loss can be high.

6. Evaporator System Operation

Today, most commercial-scale evaporation processes operate continuously. This is advantageous for system control since steady-stage operation, by definition, requires no changes in process and operating parameters and conditions during the entire duration of the operation. However, if the task involves evaporating small quantities of solution, then, in many cases, batchwise operation may be referred over the continuous. An evaporation system for batchwise operations differs from a continuous evaporator design essentially in that a comparatively large equipment volume is necessary to hold the initial charge of solution to be evaporated. However, due to the often more favorable heat-transfer conditions, the heat-exchange surface in the evaporator heating element proves to be less than that for a comparably operating continuous evaporator. In intermittent operations, the final concentration and, with it, a low heat-transfer coefficient, is the case only at the end of the operating run. For continuous operation, the same conditions for low heat-transfer coefficient apply during the entire operating run. Moreover, in batchwise operations, the time-average increase in boiling point is less than that obtaining for continuous operation at the same end concentration. Thus, if the heating steam temperature is the same for both cases, a greater effective temperature difference is available for batch operation. For these reasons, batch operation is still common even for medium-sized evaporator capacities.

In general, precise process engineering calculations prove to be somewhat more difficult for batch evaporators than those for the steady-state mode. For batch operation, namely, the concentration and with it the boiling temperature and also the film heat-transfer coefficient for the boiling liquid change continuously during the course of a run. This is true also for the effective temperature difference between heating steam and boiling liquid when heating steam temperature is constant. Further, with simple batch evaporation, the inventory of solution in the system decreases with time.

7. Crystallization by Evaporation and by Evaporation with Reduced Pressure Flashing

The enrichment of solids in solutions by evaporating the solvent covers a broad scope among thermal separation processes. In many cases, however, just thickening to higher concentrations alone does not suffice. More often, the objective is to recover the dissolved solid material in virtually pure form, isolating it completely from the solvent. This job cannot readily be done by adhering strictly to the evaporator equipment arrangements so far discussed. These have been conceived for a concentrated product that flows and is pumpable. The design features may need modification, and the method of operation may need alternation especially when processing solutions whose solubility characteristics make crystallization a possible method for separating materials. In principle, all salt solutions fall into this classification in the higher concentration ranges.In the field of evaporator engineering, evaporative crystallization (Fig. 31) and crystallization by evaporation with reduced pressure flashing (Fig. 32) have a special position among separation processes. In practice, frequently the latter is also called vacuum cooling crystallization. With intelligent application, both processes can lead to an economical system design concept. Now, if the solubility of the substance to be crystallized depends only slightly on the temperature, then, in general, the evaporative crystallization process (Fig. 31) would be used. However, crystallization by evaporation with reduced pressure flashing (Fig. 32) is a suitable separation process for preparing crystalline substances whose solubility in the solvent is strongly dependent on temperature.

Figure 31. Process steps in evaporative crystallization

Figure 32. Process steps in crystallization by reduced pressure flash evaporation

Figure 33 shows the scheme for a crystallizer installed mainly in evaporative crystallization systems in combination with an independent external evaporator heating element. Recycling the clear solution and controlling product drawoff hold the degree of supersaturation within the desired limits. Depending on the nature of the feed material, the crystal reaches a size in the range 0.5 – 3 mm.

In designing systems for evaporative crystallization and crystallization by evaporation with reduced pressure flashing, the information in the above chapters, relative to sizing the heat exchangers and vapor separation chambers as well as the ancillary equipment, can be helpful. However, for a good critical examination of the processes occurring in the crystallization characterizing zones and their influence on equipment sizing, a thorough study is absolutely necessary. This is especially the case for troublesome products which show a tendency toward severe salting of the walls of the equipment. For this, the specialized technical literature offers valuable advice.

1. Introduction

Separation of individual substances in a homogeneous liquid mixture or complete fractionation of such mixtures into their components is an important step in many production processes. Different separation procedures can be used for this purpose, but distillation is the most important industrial method.

Distillation utilizes a very simple separation principle based on the development of intimate contact between the homogeneous mixture and a second phase, which thereby allows mass transfer to occur between phases. The thermodynamic conditions are chosen so that only the component to be separated enters the second phase. The phases are subsequently separated; one of them contains the desired substance, and the other consists of a mixture that is largely free of this substance.

Three steps are always involved in industrial implementation of this separation principle:

1) Creation of a two-phase system
2) Mass transfer between phases
3) Separation of the phases

A large number of separation techniques utilize this very effective principle or modifications thereof. Absorption, desorption, evaporation, condensation, and distillation involve a gaseous and a liquid phase; solvent extraction uses two liquid phases. Separating techniques that utilize a fluid phase and a solid phase are adsorption, crystallization, drying, and leaching.

In most of these separations, the necessary two-phase system is created by adding an auxiliary phase to the mixture; the diluted substances to be separated collect with the auxiliary agent. However, in distillation, the second phase is produced by partial vaporization of the mixture. Hence, the use of an auxiliary substance, which usually requires laborious recovery, can be avoided, and the components to be separated can be recovered as pure substances. Indeed, distillation requires energy only in the form of heat, which can subsequently be removed from the system, this is another important advantage.

Historical. Distillation is a very old separation method; chemists pioneered its use in Alexandria in the first century A.D. [7]. Around the eleventh century, distillation was used for the first time in northern Italy to produce alcoholic beverages. The development of distillation equipment has been influenced tremendously by this field of application. Distillation equipment taken from "The Alchemy of Andreas Libavius" dating from 1597 is illustrated in Figure 1 [8]; it was used for the batch distillation of alcohol. Heat was applied to the liquid contents of the boiler (a) built into the oven (b), and the vapor formed was allowed to condense in two coolers (c). Cooling water was changed periodically. The only visible process was the condensate dripping into the receiver (d). Hence, this separation technique was named after the Latin word *destillare*, which means dripping or trickling down.

Even in early times, the fact was known that an even higher alcohol content could be attained by using a second distillation step. In the apparatus shown in Figure 1 two distillations could be carried out simultaneously. Condensate from the first distillation was returned to the headpiece (e), the so-called *Rectificatorium,* which

was heated with vapor rising from the boiler. The vapor thus produced was also condensed in the two coolers (c). A liquid with a higher alcohol content was then collected in a second receiver (f). The term *rectification* is derived from this process which, especially in Europe, is used to describe multistage distillation. The Latin words *recte facere* mean to rectify or improve. Indeed, to this day, rectification refers to the process by which a further concentration change is achieved after the first evaporation step.

Figure 1. Distillation and rectification equipment taken from "The Alchemy of Andreas Libavius," 1597 [8]
a) Boiler; b) Oven; c) Coolers; d) Receiver; e) Headpiece; f) Receiver

The vapor and liquid are brought into intimate contact by countercurrent flow and mass exchange occurs because the two phases are not in thermodynamic equilibrium. The phases produced during rectification are formed by evaporation and condensation of the initial mixture. The separation of a liquid mixture into its pure components can be controlled solely via the heat supply.

The basis for planning rectification is a knowledge of the *vapor – liquid equilibrium.* The separation achieved depends primarily on the concentration of the individual substances in the vapor and liquid phases. The principles of vapor – liquid equilibrium are discussed in Chapter 2; special attention is paid to the equilibria of ternary and higher mixtures.

Thermodynamic analysis of distillation and rectification is essential to establish the optimal conditions for mass transfer. The decisive factor is the driving force for mass transfer, i.e., the difference between the actual concentrations of the substances and their equilibrium concentrations. Operating conditions should ensure that this difference is sufficiently large. Appropriate relationships and methods are described in Chapters 3, 4, and 5. Examples of industrially important separation processes and energy requirements are discussed in Chapters 6 and 7, respectively.

In distillation and rectification, separation is achieved by bringing two phases into intimate contact. Hence, in practice, the problems caused by multiphase flow and mass transfer between phases must be confronted. Although the mathematical interrelationships of multiphase flow have been studied systematically from the viewpoint of fluid mechanics, often only empirical results are available for practical equipment design, as described in Chapter 8.

2. Vapor – Liquid Equilibrium

If vapor and liquid are in intimate contact for a long period of time, equilibrium is attained between the two phases. This means that no net flow of heat, mass, or momentum occurs across the phase boundary. The complete formulation for a system at equilibrium is as follows:

Thermal equilibrium	$T'' = T'$
Mechanical equilibrium	$p'' = p'$
Composition equilibrium	$y_i* = f(x_i \ldots)$

where T is the absolute temperature, p the pressure, y_i* the mole fraction of component i in the vapor phase at phase equilibrium, and x_i the mole fraction of i in the liquid phase. Single and double primes denote the liquid and vapor phases, respectively. The mass equilibrium between vapor and liquid is of primary importance in separation by distillation and rectification.

2.1. Empirical Findings in Vapor – Liquid Equilibrium

The most important empirical findings pertaining to the vapor – liquid equilibrium of binary and ternary mixtures are discussed below.

2.1.1. Binary Mixtures

Experimental phase equilibria measured at moderate pressure for binary systems composed of substances a and b are shown in Figure 2 [9].

In the upper row, total and partial pressures are plotted vs. the mole fraction of substance a in the liquid (x_a) at constant temperature. Substance a is more volatile than substance b and thus has a higher vapor pressure and a lower boiling point. The middle row shows boiling points (boiling point or bubble point line) and condensation temperatures (dew point line) plotted against the liquid and vapor compositions at constant pressure. The lower row is the concentration of a in the vapor phase (y_a) plotted vs. its concentration in the liquid phase (x_a) at constant pressure.

Significant differences in the behavior of these binary systems at equilibrium are due to the varying forces of interaction between the two molecular species a and b. Mixtures in which molecules of a and b repel each other are shown on the left side of Figure 2. Both substances undergo an increase in partial pressure p' of the liquid phase. According to the Clausius – Clapeyron relationship, this increase in vapor pressure leads to a decrease in boiling point. In the 1-butanol – water system, repulsive forces between the molecules are so strong that separation into two liquid phases occurs at intermediate concentration ranges.

Binary mixtures shown on the right side of Figure 2 exhibit exactly the opposite behavior. Molecules of substances a and b attract each other and tend to form complexes. This leads to a decrease in partial pressure p' and thus to an increase in boiling point.

In the binary mixture benzene – toluene shown in the center of Figure 2, forces of interaction between the molecular species a and b are negligible. A molecule a does not "know" whether it is colliding with an identical molecule or with a molecule b of the other substance. Such mixtures are known as *ideal mixtures*; their phase equilibria can be represented by very simple equations (see Section 2.2).

The conditions at which the vapor and liquid compositions are equal (i.e., $y = x$) are very important. Such mixtures, known as *azeotropic mixtures,* have a minimum or a maximum boiling point. In a minimum-boiling azeotrope the molecular species repel each other, whereas in a maximum-boiling azeotrope they attract each other. If the azeotrope occurs in the composition range in which the two liquids are immiscible, phase splitting occurs and a heterogeneous azeotrope is formed. A heterogeneous azeotrope is always minimum boiling.

A mixture of close-boiling components tends to form an azeotrope when the chemical structures of the components are dissimilar. Binary mixtures with two azeotropes (one minimum and one maximum) have been observed occasionally, e.g., perfluorobenzene – benzene (cf. Fig. 6 H).

The influence of pressure on the phase equilibrium of a mixture of nitrogen and methane is shown in Figure 3 A. At higher pressures, differences between the concentrations of the vapor y and the liquid x decrease markedly. When the critical pressure of the pure substances is exceeded, they can no longer be liquefied in the supercritical region. However, mixtures of supercritical vapors can split into two phases, as shown in Figure 3 B. The region in which this can occur is restricted by the convergence pressure curve, which represents the critical points of mixtures of the two substances and may pass through a maximum.

2.1.2. Ternary Mixtures

The phase equilibrium of ternary mixtures is depicted conveniently on a triangular diagram, in which the corners represent the pure substances a, b, and c.

In Figure 4, the mole fraction of component i in the liquid, x_i, is represented by the basic grid and the vapor mole fraction y_i* in equilibrium with the liquid is shown as parameter curves. For ideal mixtures with constant relative volatilities α_{ik} (see Section 2.2.2), these parameter curves are straight lines. However, for nonideal systems plots of y_i* do not yield straight lines, and the entire representation becomes confusing. In addition, the azeotropic points, which are very important in rectification, are difficult to recognize.

The use of *distillation curves* is more effective. If an initial liquid concentration of component i, x_{i0}, is assumed, the equilibrium vapor concentration $y_{i0}*$ is determined. The vapor is then assumed to be totally condensed. Thus, a new liquid of composition $x_{i1} = y_{i0}*$ is obtained and marked on the triangular diagram. The vapor state $y_{i1}*$ in equilibrium with this liquid state x_{i1} is, in turn, determined and so on. A series of liquid states $x_{i1}, x_{i2}, x_{i3}, \ldots$, is finally obtained; the

Figure 2. Phase equilibria of five binary mixtures composed of substances a and b [9]
Substance a is more volatile than substance b. The dashed lines in the upper row represent ideal behavior. Temperature and vapor concentration equilibria (middle and bottom rows) were measured at constant pressure (0.1 MPa). Shaded area represents the liquid immiscibility composition range. Azeotropic points are indicated by open circles.
p_a = partial pressure of a; p_b = partial pressure of b; x_a = mole fraction of a in liquid phase; y_a = mole fraction of a in vapor phase

Figure 3. Influence of pressure p on the phase equilibrium of nitrogen and methane
A) Boiling point lines (——) and dew point lines (– – –) of nitrogen – methane mixtures; x_{N_2} = mole fraction of nitrogen in the liquid phase; y_{N_2} = mole fraction of nitrogen in the vapor phase; B) Critical points of nitrogen (a), methane (b), and their mixtures (convergence pressure curve – – –)

composition difference in each case represents an equilibrium step. These liquid states can be joined together to give a distillation curve. This process leads to step-by-step enrichment of the more volatile component, which is accompanied by a decrease in boiling point.

Several distillation curves are shown in Figure 5. The direction of boiling point decrease is indicated by an arrow. The sides of the triangle, which represent binary mixtures, can also be interpreted as distillation curves. The dots on one of the curves represent the sequence of distinct liquid states from one equilibrium stage to the next. Large spaces between points depict regions with large differences in concentration between the liquid and the corresponding vapor.

Distillation curves for nine ternary systems are shown in Figure 6. In each case, the lowest boiling substance (a) is at the top of the triangle, the medium boiler (b) is at the right side, and the high boiler (c) is at the left.

Mixture A exhibits almost ideal behavior. The distillation curves proceed from the high-boiling substance c to the low boiler a. At the same time, the medium-boiling component b exhibits a more or less pronounced concentration maximum.

A binary minimum azeotrope between the low- and medium-boiling substances is formed in mixture B. Indeed, the lowest boiling temperature of the system is at this azeotrope. As a result, all distillation curves starting from the high boiler c tend toward this binary azeotrope. Analogous behavior is observed with mixture C in which a binary maximum azeotrope occurs between the medium-boiling substance b and the high boiler c. The highest boiling temperature of the system is at this azeotrope. All distillation curves start with this temperature maximum and end at the temperature minimum, i.e., at the low boiler a.

Mixture D shows a binary a – b maximum azeotrope. The distillation curves, starting from

Figure 4. Representation of the phase equilibrium of the ternary mixture nitrogen – argon – oxygen at 131 kPa
The uniformly divided grid of the triangular diagram represents the liquid composition x_{Ar}, x_{O_2}, and x_{N_2}. The bold and dashed lines indicate equilibrium vapor mole fractions of oxygen ($y*_{O_2}$) and argon ($y*_{Ar}$), respectively. Temperatures indicate boiling points of the pure components.

the high boiler c, first proceed toward this azeotrope and then turn toward the low boiler a or the medium boiler b. Thus, this ternary system is divided into two areas whose distillation curves have different end points. The distillation curve that forms the boundary between these two areas is called the *distillation boundary.* In this case, the boundary runs from the pure high-boiling substance c to the binary maximum azeotrope.

A distillation boundary also arises when a binary mixture of a medium-boiling substance b and a high boiler c produces a minimum azeotrope (mixture E). In this case, a heterogeneous azeotrope is formed because it lies within the liquid immiscibility range. The distillation curves for mixture E have two starting points, but they all end at the low-boiling substance a. The distillation boundary runs from the heterogeneous azeotrope to the low boiler a.

Two binary minimum azeotropes occur in mixture F where the distillation boundary runs between the two azeotropes. This ternary system is thus divided into two areas, the distillation curves in each area having different starting points.

In mixtures G and H in Figure 6, a saddle-point ternary azeotrope is formed in addition to the two azeotropes. Distillation curves do not start or end at the saddle point. Instead, they proceed from different directions toward this point and then turn away. Distillation boundaries divide both ternary systems into four distillation fields. The binary mixture of the low boiler a and the medium-boiling substance b in mixture H forms a minimum- and a maximum-boiling binary azeotrope.

Figure 5. Representation of the phase equilibrium of the ternary mixture nitrogen – argon – oxygen at 131 kPa by distillation curves
The distillation curves start at the component with the highest boiling point and end at the component with the lowest boiling point. The direction of decreasing temperature is indicated by arrows. Distinct equilibrium states are shown on one curve as dots.

An immiscibility range with a heterogeneous azeotrope and two binary minimum azeotropes occur in system I. In addition, a ternary minimum azeotrope with the lowest boiling temperature of the entire system is formed. Thus, all distillation curves originate at the pure substances and converge at the ternary azeotrope. The azeotropes are connected by distillation boundaries giving rise to three distillation fields.

Distillation curves facilitate clear representation of the phase equilibria of ternary systems. Reliable vapor – liquid equilibrium data are essential for planning distillation and rectification processes. As shown in Figure 5, determination of the distance from one equilibrium stage to the next is also very useful. However, knowledge of the boiling temperatures of the points indicated (pure substances and azeotropes) and of the directional arrows on the distillation curves is usually sufficient for process design. The position of the distillation boundaries, which divide the ternary system into different fields, is of considerable importance. These boundaries always connect points of minimum or maximum temperature, which are usually the high boiler, the low boiler, and binary or ternary azeotropes. Knowledge of these points alone may be sufficient to estimate the approximate positions of distillation boundaries; phase equilibrium data are not always required.

The boiling points of a ternary mixture can be represented three-dimensionally where the distillation boundaries form either a ridge or a valley. Graphical representation of the contours of the temperature surface as a function of liquid composition in the system acetone – chloroform – methanol (G in Fig. 6) is shown in Figure 7. The distillation boundaries intersect at a saddle-point indicating a ternary azeotrope.

The existence of ternary azeotropes is of considerable importance and can be checked by using the following equation [10]:

$$2\,(N_3 - S_3) + N_2 - S_2 + N_1 = 2 \tag{2.1}$$

where N is the number of nodes at which distillation curves either start or end, and S is the number of saddle points at which distillation curves either meet or split, usually combined with a sudden change of direction. The subscripts 1, 2, and 3 indicate a pure substance, a binary mixture, and a ternary mixture, respectively. For example, mixture A in Figure 6 exhibits only two nodes for pure substances. Thus $N_1 = 2$ and Equation (2.1) balances. The distillation curves in mixture I start at all three pure substances; thus $N_1 = 3$. All three binary azeotropes are saddle points at which two distillation curves meet and then break away by changing direction. Therefore, $S_2 = 3$ and Equation (2.1) becomes

$$2\,(N_3 - S_3) + 0 - 3 + 3 = 2 \tag{2.2}$$

In other words, ternary azeotropes must exist. The simplest solution to this equation is $N_3 = 1$ and $S_3 = 0$; i.e., one ternary azeotrope exists. Several ternary azeotropes can occur in this system only if ternary saddle points exist at the same time, which however is not the case.

Analogously, for mixture G in Figure 6, $N_1 = 1$ and $N_2 = 3$; the following equation is obtained:

$$2\,(N_3 - S_3) + 3 - 0 + 1 = 2 \tag{2.3}$$

The simplest solution to this equation is $S_3 = 1$. In other words, one ternary saddle point

Figure 6. Phase equilibria of nine ternary mixtures at 101.3 kPa
The distillation curves proceed from a temperature maximum to a temperature minimum. Distillation boundaries are represented by bold lines. Shaded areas indicate the presence of two liquid phases. Open circles denote azeotropic points.

exists, which corresponds to the experimental findings.

The preceding examples show that Equation (2.1) can be employed to predict the existence of ternary azeotropes by using a knowledge of binary marginal mixtures. Although several solutions may exist, the simplest is probably correct.

Figure 7. Boiling point surface as a function of liquid composition for the ternary acetone – chloroform – methanol system
Temperatures indicate boiling points of pure substances and azeotropic points.

2.2. Empirical Laws of Vapor – Liquid Equilibrium

Vapor – liquid equilibria are best understood with the help of simple, empirical laws which may, however, only apply within certain limits.

Dalton's law describes vapor systems:

$$p_i''/p''=n_i''/n''=V_i''/V'' \tag{2.4}$$

where p'' is the pressure, n'' the number of moles of substance, and V'' the volume of the vapor. The subscript i denotes component i. Because $n''_i/n''=y_i$ (where y_i is the mole fraction of component i in the vapor), this law can be expressed as:

$$p_i''=y_i\cdot p'' \tag{2.5}$$

Dalton's law generally holds at low pressure ($p''\ll p_{\mathrm{cr}}$, where p_{cr} is the critical pressure). At higher pressure, however, it may require modification. Instead of using pressure p, the equation is written in terms of fugacity f:

$$f_i''=y_i\cdot f'' \tag{2.6}$$

The fugacity f can be determined from the fugacity coefficient $\varphi=f/p$ (Section 2.4).

According to *Raoult's law,* the partial pressure p_i' of component i from a liquid mixture is

$$p_i'=x_i\cdot p_i^0 \tag{2.7}$$

Hence, the partial pressure p_i' depends only on the vapor pressure $p_i{}^0$ of pure component i and its liquid mole fraction x_i; it is not affected by the nature of other substances in the liquid mixture. Raoult's law holds only as long as the forces of interaction between different types of molecules are equal (ideal mixture). Nonideal liquid-phase behavior (i.e., unequal interaction forces) is described by using the activity coefficient γ_i, which is defined as follows:

$$p_i'=\gamma_i\cdot x_i\cdot p_i^0 \tag{2.8}$$

The activity coefficient γ_i is highly concentration-dependent. Methods used to determine activity coefficients are described in Section 2.3.

Equations (2.7) and (2.8) apply only at temperatures below the critical temperature ($T<T_{\mathrm{cr}}$) because the substance does not exert a vapor pressure at higher temperatures. When $T>T_{\mathrm{cr}}$, *Henry's law* is applied instead of Raoult's law:

$$p_{\mathrm{i}}'=H_{ij}\cdot x_i \tag{2.9}$$

where H_{ij} is the Henry coefficient for substance i in solvent j. Again, a correction must be made for nonideal mixtures by using the activity coefficient γ_i:

$$p_i'=H_{ij}\cdot\gamma_i\cdot x_i \tag{2.10}$$

This relationship is analogous to Raoult's law, except that the proportionality constant is not the vapor pressure $p_i{}^0$, but Henry's coefficient H_{ij}.

2.2.1. Equilibrium Constant

The equilibrium constant for component i, K_i, is commonly used to represent phase equilibrium data, especially in multicomponent mixtures. It is defined as

$$K_{\mathrm{i}} = y_i^*/x_i \tag{2.11}$$

Because at phase equilibrium

$$p_i'' = p_i' \tag{2.12}$$

then from Equations (2.5) and (2.7),

$$K_i = p_i^0/p \text{ or } K = p_i^0 \cdot \gamma_i/p \tag{2.13}$$

Similarly, at temperatures above the critical point,

$$K_i = H_{ij}/p \text{ or } K = H_{ij} \cdot \gamma_i/p \tag{2.14}$$

Both the vapor pressure ${p_i}^0$ and Henry's coefficient H_{ij} are strongly dependent on temperature. Hence, the equilibrium constant K_i can be employed only at known temperatures.

2.2.2. Equilibrium Curve

For binary systems consisting of components a and b,

$$y_{\mathrm{a}}^* = \frac{p_{\mathrm{a}}'}{p_{\mathrm{a}}' + p_{\mathrm{b}}'} = \frac{x_{\mathrm{a}} \cdot p_{\mathrm{a}}^0}{x_{\mathrm{a}} \cdot p_{\mathrm{a}}^0 + x_b \cdot p_{\mathrm{b}}^0} \tag{2.15}$$

Since the vapor pressures of the pure components p_{a}^0 and p_{b}^0 are highly temperature-dependent, this equation applies only at constant temperature. However, the ratio $p_{\mathrm{a}}^0/p_{\mathrm{b}}^0$ is often independent of temperature; therefore, vapor – liquid equilibria are frequently expressed in this form as the relative volatility α:

$$\alpha_{\mathrm{ab}} = p_{\mathrm{a}}^0/p_{\mathrm{b}}^0 \tag{2.16}$$

From the equation $x_{\mathrm{b}} = 1 - x_{\mathrm{a}}$,

$$y_{\mathrm{a}}^* = \frac{\alpha_{\mathrm{ab}} \cdot x_{\mathrm{a}}}{1 + (\alpha_{\mathrm{ab}} - 1) \cdot x_{\mathrm{a}}} \tag{2.17}$$

This relationship is called the *equilibrium curve* and is valid when the temperature is constant. If α_{ab} does not vary with temperature, Equation (2.17) can also be employed at other temperatures at constant pressure; this is particularly important in distillation and rectification.

Similarly, for ternary systems consisting of components a, b, and c:

$$y_{\mathrm{a}}^* = \frac{p_{\mathrm{a}}'}{p_{\mathrm{a}}' + p_{\mathrm{b}}' + p_{\mathrm{c}}'} = \frac{x_{\mathrm{a}} \cdot p_{\mathrm{a}}^0}{x_{\mathrm{a}} \cdot p_{\mathrm{a}}^0 + x_{\mathrm{b}} \cdot p_{\mathrm{b}}^0 + x_{\mathrm{c}} \cdot p_{\mathrm{c}}^0} \tag{2.18}$$

Substituting $\alpha_{\mathrm{ac}} = p_{\mathrm{a}}^0/p_{\mathrm{c}}^0$, $\alpha_{\mathrm{bc}} = p_{\mathrm{b}}^0/p_{\mathrm{c}}^0$, and $x_{\mathrm{c}} = 1 - x_{\mathrm{a}} - x_{\mathrm{b}}$ gives

$$y_{\mathrm{a}}^* = \frac{x_{\mathrm{a}} \cdot \alpha_{\mathrm{ac}}}{1 + (\alpha_{\mathrm{ac}} - 1) \cdot x_{\mathrm{a}} + (\alpha_{\mathrm{bc}} - 1) \cdot x_{\mathrm{b}}} \tag{2.19}$$

$$y_{\mathrm{b}}^* = \frac{x_{\mathrm{b}} \cdot \alpha_{\mathrm{bc}}}{1 + (\alpha_{\mathrm{ac}} - 1) \cdot x_{\mathrm{a}} + (\alpha_{\mathrm{bc}} - 1) \cdot x_{\mathrm{b}}}$$

The general equation for multicomponent mixtures is

$$y_i^* = \frac{\alpha_{ik} \cdot x_i}{1 + \sum_{j=1}^{k-1} (\alpha_{jk} - 1) \cdot x_j} \tag{2.20}$$

for component 1 to $k - 1$ where k refers to the highest boiling substance. In nonideal systems, the activity coefficient γ_i must be incorporated into the equations.

2.2.3. Distillation Curve

The distillation curves of ideal mixtures are very important in representing the phase equilibria of ternary mixtures and can be expressed by a simple equation. Rearrangement of Equation (2.17) gives the equilibrium curve of ideal mixtures in the following form:

$$\frac{y_0^*}{1 - y_0^*} = \alpha \cdot \frac{x_0}{1 - x_0} \tag{2.21}$$

where the subscript 0 denotes the initial state.

Total condensation of the vapor arising from the liquid is assumed in determining the paths of distillation curves (see Section 2.1.2). A new liquid with the concentration $x_1 = y*_0$ is obtained. Thus:

$$\frac{x_1}{1 - x_1} = \alpha \cdot \frac{x_0}{1 - x_0} \tag{2.22}$$

Similarly, $x_2 = y*_1$ is valid for the second step, giving:

$$\frac{x_2}{1 - x_2} = \alpha \cdot \frac{x_1}{1 - x_1} = \alpha^2 \cdot \frac{x_0}{1 - x_0} \tag{2.23}$$

For the nth step,

$$\frac{x_n}{1-x_n}=\alpha^n\frac{x_0}{1-x_0} \tag{2.24}$$

Rearrangement gives

$$x_n=\frac{\alpha^n\cdot x_0}{1+(\alpha^n-1)\cdot x_0} \tag{2.25}$$

This equation is similar to the equilibrium relationship (Eq. 2.17), except that here the term α^{n} replaces α. Thus, for ternary mixtures,

$$x_{\mathrm{a}n}=\frac{\alpha_{\mathrm{ac}}^n\cdot x_{\mathrm{a0}}}{1+(\alpha_{\mathrm{ac}}^n-1)\cdot x_{\mathrm{a0}}+(\alpha_{\mathrm{bc}}^n-1)\cdot x_{\mathrm{b0}}} \tag{2.26}$$

$$x_{\mathrm{b}n}=\frac{\alpha_{\mathrm{bc}}^n\cdot x_{\mathrm{b}}}{1+(\alpha_{\mathrm{ac}}^n-1)\cdot x_{\mathrm{a0}}+(\alpha_{\mathrm{bc}}^n-1)\cdot x_{\mathrm{b0}}}$$

Similarly, for multicomponent mixtures, the distillation curve is represented by

$$x_{in}=\frac{\alpha_{ik}^n\cdot x_{i0}}{1+\sum_{j=1}^{k-1}\left(\alpha_{jk}^n-1\right)\cdot x_{j0}} \tag{2.27}$$

The distillation curves of ideal mixtures with a constant relative volatility α_{ik} can easily be calculated by using these equations.

2.3. Calculation of Phase Equilibrium from Excess Enthalpy

Deviations from ideal behavior occur in the liquid phase rather than in the gas phase. As a result of smaller intermolecular distances, the forces of interaction between molecules in the liquid are considerably stronger. In contrast, the vapor phase can be assumed to be ideal at moderate pressure.

Real liquid-phase behavior is usually described by means of the activity coefficient γ (Eq. 2.8). However, the activity coefficients of individual components *i* of a liquid mixture are not independent of each other, as formulated by the *Gibbs – Duhem equation* [11]:

$$\sum x_i\cdot \mathrm{d}\ln\gamma_i=0 \tag{2.28}$$

For binary mixtures, the Gibbs – Duhem equation requires that both activity coefficients are either <1 or >1 and that they exhibit oppositely directed gradients when plotted as a function of the concentration.

Equation (2.28) is a fundamental thermodynamic equation which must always be satisfied and has long been used to check the thermodynamic consistency of vapor – liquid equilibrium data [11].

To obtain a relationship for the concentration dependency of the activity coefficient γ_i, starting with one value of state of the entire mixture is useful. In this way, a thermodynamically consistent formulation of phase equilibrium is attained automatically. Mixing processes can be described most simply by using the free enthalpy g [11]. The free enthalpy change for the mixing of ideal liquids, Δg^{id}, is

$$\Delta g=\hat{R}\cdot T\cdot\sum x_{\mathrm{i}}\cdot\ln x_{\mathrm{i}}id \tag{2.29}$$

where $\hat{R}$ is the universal gas constant. Analogously, for nonideal mixtures,

$$\Delta g=\hat{R}\cdot T\cdot\sum x_i\cdot\ln x_i+\hat{R}\cdot T\cdot\sum x_i\cdot\ln\gamma_i \tag{2.30}$$

The second term accounts for the nonideal behavior of the mixture and is called the free excess enthalpy Δg^{E}:

$$\Delta g=\hat{R}\cdot T\cdot\sum x_i\cdot\ln\gamma_i E \tag{2.31}$$

Hence,

$$\Delta g=\Delta g^{\mathrm{id}}+\Delta g^{\mathrm{E}} \tag{2.32}$$

Differentiation of the equation for the free excess enthalpy Δg^{E} gives relationships for the activity coefficients γ_i of the individual components of a mixture. In general,

$$\ln\gamma_i=\frac{1}{\hat{R}\cdot T}\left(\Delta \mathrm{g}^{\mathrm{E}}+\frac{\partial\Delta g^{\mathrm{E}}}{\partial x_i}-\sum_{k=1}^{n}x_k\cdot\frac{\partial\Delta g^{\mathrm{E}}}{\partial x_k}\right) \tag{2.33}$$

For a binary mixture of substances a and b,

$$\ln\gamma_{\mathrm{a}}=\frac{1}{\hat{R}\cdot T}\left(\Delta g^{\mathrm{E}}+\frac{\partial\Delta g^{\mathrm{E}}}{\partial x_{\mathrm{a}}}-x_{\mathrm{a}}\cdot\frac{\partial\Delta g^{\mathrm{E}}}{\partial x_{\mathrm{a}}}\right) \tag{2.34}$$

Using $x_{\mathrm{b}}=1-x_{\mathrm{a}}$ finally gives

$$\ln\gamma_{\mathrm{a}}=\hat{R}\cdot T\left(\Delta \mathrm{g}^{\mathrm{E}}+x_{\mathrm{b}}\cdot\frac{\partial\Delta g^{\mathrm{E}}}{\partial x_{\mathrm{a}}}\right) \tag{2.35}$$

Similarly,

$$\ln\gamma_{\mathrm{b}}=\hat{R}\cdot T\left(\Delta g^{\mathrm{E}}-x_{\mathrm{a}}\cdot\frac{\partial\Delta g^{\mathrm{E}}}{\partial x_{\mathrm{a}}}\right) \tag{2.36}$$

Relationships for the free excess enthalpy Δg^{E}, which satisfy the condition $\Delta g^{\mathrm{E}}=0$ for $x_i=1$, are required to calculate the activity coefficient γ_i of a mixture from Equation (2.35). Empirical correlations containing two or three correlating parameters are generally used for binary mixtures [11]. However, improved theoretical formulations, usually based on the concept of local composition or on the increment method, are being employed increasingly. An example is the *Wilson equation* for a binary mixture [11]:

$$\frac{\Delta g^{\mathrm{E}}}{\hat{R}\cdot T}= -\left[x_{\mathrm{a}}\cdot\ln\left(x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}\right)+x_{\mathrm{b}}\cdot\ln\left(x_{\mathrm{b}}+A_{\mathrm{ba}}\cdot x_{\mathrm{a}}\right)\right] \quad (2.37)$$

where A_{ab} and A_{ba} are the Wilson coefficients for the binary pair a – b. Hence, the activity coefficients can be represented by

$$\ln\gamma_{\mathrm{a}}= 1-\ln\left(x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}\right)-\frac{x_{\mathrm{a}}}{x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}}-\frac{A_{\mathrm{ba}}\cdot x_{\mathrm{b}}}{x_{\mathrm{b}}+A_{\mathrm{ba}}\cdot x_{\mathrm{a}}}$$
$$\ln\gamma_{\mathrm{b}}= 1-\ln\left(x_{\mathrm{b}}+A_{\mathrm{ba}}\cdot x_{\mathrm{a}}\right)-\frac{x_{\mathrm{b}}}{x_{\mathrm{b}}+A_{\mathrm{ba}}\cdot x_{\mathrm{a}}}-\frac{A_{\mathrm{ab}}\cdot x_{\mathrm{a}}}{x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}} \quad (2.38)$$

The forces of interaction between molecules of a and b can be determined from a few measured values and are described by the coefficients A_{ab} and A_{ba}; these coefficients depend only slightly on pressure.

The Wilson equation for a ternary mixture is

$$\frac{\Delta g^{\mathrm{E}}}{\hat{R}\cdot T}= -x_{\mathrm{a}}\cdot\ln\left(x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}+A_{\mathrm{ac}}\cdot x_{\mathrm{c}}\right)-$$
$$-x_{\mathrm{b}}\cdot\ln\left(A_{\mathrm{ba}}\cdot x_{\mathrm{a}}+x_{\mathrm{b}}+A_{\mathrm{bc}}\cdot x_{\mathrm{c}}\right)-$$
$$-x_{\mathrm{c}}\cdot\ln\left(A_{\mathrm{ca}}\cdot x_{\mathrm{a}}+A_{\mathrm{cb}}\cdot x_{\mathrm{b}}+x_{\mathrm{c}}\right) \quad (2.39)$$

Therefore, the activity coefficient of substance a is

$$\ln\gamma_{\mathrm{a}}= 1-\ln\left(x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}+A_{\mathrm{ac}}\cdot x_{\mathrm{c}}\right)-$$
$$-\frac{x_{\mathrm{a}}}{x_{\mathrm{a}}+A_{\mathrm{ab}}\cdot x_{\mathrm{b}}+A_{\mathrm{ac}}\cdot x_{\mathrm{c}}}-$$
$$-\frac{A_{\mathrm{ba}}\cdot x_{\mathrm{b}}}{A_{\mathrm{ba}}\cdot x_{\mathrm{a}}+x_{\mathrm{b}}+A_{\mathrm{bc}}\cdot x_{\mathrm{c}}}-$$
$$-\frac{A_{\mathrm{ca}}\cdot x_{\mathrm{c}}}{A_{\mathrm{ca}}\cdot x_{\mathrm{a}}+A_{\mathrm{cb}}\cdot x_{\mathrm{b}}+x_{\mathrm{c}}} \quad (2.40)$$

The activity coefficients of substances b and c are obtained analogously.

The Wilson equation for a multicomponent mixture consisting of n components is

$$\frac{\Delta g^{\mathrm{E}}}{\hat{R}\cdot T}= -\sum_{i}^{n} x_i\cdot\ln\left(\sum_{j}^{n} A_{ij}\cdot x_j\right);$$
$$\text{where } A_{ii}=1 \quad (2.41)$$

Hence, the activity coefficients are given by

$$\ln\gamma_i= 1-\ln\left(\sum_{j}^{n} A_{ij}\cdot x_j\right)-$$
$$-\sum_{l}^{n}\frac{A_{li}\cdot x_l}{\sum_{j}^{n} A_{lj}\cdot x_j} \quad (2.42)$$

Even in ternary and higher systems, the Wilson equation contains only the interaction parameters A_{ij} for the binary mixtures involved. Hence, prediction of the phase equilibria of multicomponent systems from binary data is possible. The Wilson equation has proved its worth in practice; the majority of distillation curves presented in Figure 6 were calculated by using this equation. However, unlike the Uniquac (UNiversal QUAsiChemical) equation [12], it is not applicable to systems that undergo phase splitting. Systems E and I in Figure 6 were calculated with the Uniquac equation.

2.4. Calculation of Phase Equilibrium from Equations of State

The method for calculating phase equilibrium from the excess enthalpy, described in Section 2.3, can be applied to systems that are nonideal in the liquid phase only. However, because Dalton's law does not hold at higher pressures, the vapor phase may also deviate from ideal behavior. An effective way of calculating phase equilibria at high pressure is based on equations of state for the fluid, which describe both the vapor and the liquid phases with sufficient accuracy. Partial fugacities f_i are used instead of partial pressures p_i. At equilibrium,

$$f_i''=f_i' \quad (2.43)$$

where f_i'' and f_i' are the fugacities of component i in the vapor and liquid phases, respectively. By analogy with Equation (2.6) and using the fugacity coefficients $\varphi_i=f_i/p_i$, the following equation is obtained:

$$\varphi_i'' \cdot y_i \cdot p = \varphi_i' \cdot x_i \cdot p \tag{2.44}$$

Hence, the equilibrium constant K_i is

$$K_i = \varphi_i' / \varphi_i'' \tag{2.45}$$

Thus, the equilibrium constant can be calculated from fugacity coefficients determined in the two phases. The following rigorous relationship is obtained by using the laws of thermodynamics [11]:

$$\hat{R} \cdot T \cdot \ln\varphi_i = \int_0^p \left(\hat{V}_i - \hat{R} \cdot T/p\right) \cdot \mathrm{d}p \tag{2.46}$$

where the partial molar volume

$$\hat{V}_i = (\partial V / \partial n_i)_{p,T,n_{j \neq i}}$$

and the total volume

$$V = \hat{V}_\mathrm{i} \cdot \sum n_i$$

The molar volume $\hat{V}$ and the derivative $\partial V/\partial n1$ are determined by using a suitable equation of state.

The real behavior of pure fluids can be described by the compressibility factor Z:

$$Z = p \cdot \hat{V} / \left(\hat{R} \cdot T\right) \tag{2.47}$$

For ideal vapors, $Z = 1$. Deviations from this value are directly proportional to the degree of nonideal behavior.

Two different types of equations of state describe the real behavior of pure fluids. One is based on the van der Waals equation:

$$Z = \hat{V} / \left(\hat{V} - \bar{b}\right) - \bar{a} / \left(\hat{R} \cdot T \cdot \hat{V}\right) \tag{2.48}$$

The coefficients $\bar{a}$ and $\bar{b}$ can be interpreted as representing interaction forces and molecular volume, respectively.

The second type of expression is based on the virial equation

$$Z = 1 + B/\hat{V} + C/\hat{V}^2 + \ldots \tag{2.49}$$

Intermolecular forces are described by the virial coefficients B, C, etc., which for pure fluids are a function only of temperature.

Both types of equations have been improved by numerous modifications to obtain a pressure – volume – temperature equation that is applicable to both vapor and liquid phases. Equations of state used to determine phase equilibria must correctly represent mixtures of substances and must include equations for the pure components as special cases. Equations of state for mixtures are generally derived from equations of state for the pure substances by using concentration-dependent coefficients. However, theoretical methods are not available, and empirical rules of combination are used. In principle, equations for excess enthalpy (see Section 2.3) can be applied successfully to the formulation of mixing rules [13].

The procedure can be illustrated by using the Soave modification of the Redlich – Kwong equation (Eq. 2.48) [14]:

$$Z = \hat{V} / \left(\hat{V} - \bar{b}\right) - \bar{a} / \left(\hat{R} \cdot T \cdot \left(\hat{V} + \bar{b}\right)\right) \tag{2.50}$$

The coefficients $\bar{a}$ and $\bar{b}$ can be determined from the critical values p_cr, T_cr, and the acentric factor ω of the pure substances.

$$\begin{aligned} \bar{a} &= 0.42747 \cdot \alpha \cdot \hat{R}^2 \cdot T_\mathrm{cr}^2 / p_\mathrm{cr} \\ \text{where } \alpha &= \left[1 + m\left(1 - \sqrt{T/T_\mathrm{cr}}\right)\right]^2 \\ m &= 0.48 + 1.574 \cdot \omega - 0.176\omega^2 \\ \bar{b} &= 0.08664 \cdot \hat{R} \cdot T_\mathrm{cr} / p_\mathrm{cr} \end{aligned} \tag{2.51}$$

The following mixing rules apply to mixtures of components i and j:

$$\bar{a} = \sum_i \sum_j x_i \cdot x_j \cdot \bar{a}_{ij}$$

Here,

$$\bar{a}_{ij} = \sqrt{\bar{a}_{ii} \cdot \bar{a}_{jj}}\,(1 - k_{ij}), \text{ where } k_{ii} = 0 \tag{2.52}$$

k_{ij} for $i \neq j$ can be found in tables [15].

$$\bar{b} = \sum x_i \cdot \bar{b}_i$$

Substituting Equation (2.50) in Equation (2.46) gives

$$\begin{aligned} ln\varphi_i = &\left[\bar{b}_i / \left(\bar{b} \cdot \hat{R} \cdot T\right)\right] \cdot \left[p \cdot v - \hat{R} \cdot T\right] - \\ &- \ln\left[p / \left(\hat{R} \cdot T\right)(v - \bar{b})\right] - \\ &- \left[a / \left(\bar{b} \cdot \hat{R} \cdot T\right)\right]\left[2/\bar{a} \cdot \Sigma\left(x_j \cdot \bar{a}_{ij}\right) - \bar{b}_i/\bar{b}\right] \cdot \\ &\cdot \ln\left[\left(v + \bar{b}\right)/v\right] \end{aligned} \tag{2.53}$$

Trial values for the concentration and molar volume of each phase must be estimated to solve this equation for each phase. Equation (2.50) is used to improve the values during iteration. The equilibrium constant K for each component can then be calculated by using Equation (2.45) to check the assumed phase concentrations. This iteration method often converges to trivial solutions. However, other available procedures require good starting values close to those of the solution [16].

2.5. Practical Determination of Phase Equilibria

Reliable phase equilibrium data are essential for the design of distillation and rectification operations. Despite the highly advanced state of mixed-phase thermodynamics, good experimental data should be used when possible. Several thousand publications on vapor – liquid equilibria are available which include complete descriptions of the p, v, T, x behavior of a system. However, the majority provide equilibrium concentrations only over a certain range of temperature and pressure. Useful data on azeotropic compositions are readily available [17], mainly in the form of data collections [15], [18–23]. Older data collections consist merely of compilations of measured values; however, newer data are subjected to a consistency test. In addition, coefficients for several equations of state or for equations for excess enthalpy are presented in [15], [23].

Data for many binary mixtures can be found in the above collections. Available data for ternary or higher mixtures over the concentration range of interest are seldom adequate. At the very best, data are provided for binary mixtures present in the system. Usually, equilibrium data are far from complete. In all these cases, the methods of thermodynamic representation of phase equilibria described in Sections 2.3 and 2.4 must be used.

Equations for excess enthalpy are useful at low pressure and when nonideal behavior occurs, mainly in the liquid phase. Equations that use binary interaction parameters to calculate the phase equilibrium of multicomponent mixtures are especially useful. These are primarily equations based on the concept of local composition. Furthermore, the incremental method permits approximation of the interaction parameters from the chemical structure of the substances involved [24].

In high-pressure systems, the liquid phase and especially the vapor phase exhibit nonideal behavior. The convergence pressure method was often used in the past [25] but has now been superseded by the more effective equations of state. Equations of state based on the virial equation have the advantage of being theoretically based for mixtures. However, these equations are valid only at reduced pressure, i.e., $p/p_{\mathrm{cr}} < 0.5$. Equations of the van der Waals type are preferred at higher pressure. Apart from empirical mixing rules, almost all equations of state contain a further binary correlating parameter (k_{ij} in Eq. 2.52), which greatly influences phase equilibrium.

Equations of state are preferred to equations for excess enthalpy, because the former permit calculation not only of phase equilibria but also of other values of state, e.g., density and enthalpy. Empirical mixing rules are not completely satisfactory because they are usually applied to both phases in the same way; this does not correspond fully to real conditions in multicomponent mixtures. The vapor – liquid equilibrium cannot yet be reliably predicted. Progress in mixed-phase thermodynamics permits only a thermodynamically consistent representation of equilibria based on relatively few experimental data.

3. Distillation

As discussed in Chapter 2, the composition of the vapor usually differs from that of the liquid from which it originates. This concentration difference between the two phases is the basis of distillation, which is a simple method of separating substances. The method involves partial evaporation of the liquid followed by condensation of the vapor. The resulting condensate is enriched in the more volatile components, in accordance with the phase equilibrium for the system at hand. Thus, the starting mixture or feed is separated into two fractions with different compositions.

3.1. Continuous Distillation

Figure 8 represents the continuous distillation of a liquid mixture. The *feed* (molar flow rate $\dot{F}$) is separated into an *overhead product* or *distillate* (molar flow rate $\dot{D}$) and a *bottom product* (molar flow rate $\dot{B}$). The composition difference between these two products depends on the phase equilibrium.

Figure 8. Continuous distillation of a binary mixture a – b A) Flow diagram showing symbols for total molar streams or flow rates ($\dot{F}$, $\dot{L}$, etc.) and mole fractions of the more volatile component a (x_F, x_D, etc.); B) A y – x diagram showing equilibrium and operating linesThe y – x diagram can be used to determine the composition of the overhead and bottom product streams ($\dot{D}$ and $\dot{B}$, respectively).

3.1.1. Continuous Distillation of Binary Mixtures

The material balance around the boiler (see Fig. 8) yields

$$\dot{F} = \dot{G} + \dot{L} \tag{3.1}$$

where $\dot{F}$, $\dot{G}$, and $\dot{L}$ are the molar flow rates of the feed, vapor, and bottom liquid, respectively. Similarly, the material balance for the more volatile feed component a of a binary mixture a – b gives

$$\dot{F} \cdot x_F = \dot{G} \cdot y + \dot{L} \cdot x \tag{3.2}$$

where x_F is the mole fraction of a in the feed, y is the mole fraction of a in the vapor, and x is the mole fraction of a in the bottom liquid. Thus,

$$y = -\dot{L}/\dot{G} \cdot x + \left(1 + \dot{L}/\dot{G}\right) \cdot x_F \tag{3.3}$$

This is the equation for a straight line with slope $-\dot{L}/\dot{G}$. When plotted on the $y-x$ diagram, it furnishes the *operating line.* The operating line intersects the $y = x$ diagonal at $x = x_F$ (Fig. 8 B).

With the closely met assumption that equilibrium exists between the vapor $\dot{G}$ and the liquid $\dot{L}$ in the boiler, (i.e., $y = y*$), the following equation holds for ideal mixtures (see Section 2.2.2):

$$y^* = \frac{\alpha \cdot x}{1 + (\alpha - 1) \cdot x} \tag{3.4}$$

where α is the relative volatility.

The parameters x and y can be determined by equating relationships (3.3) and (3.4) to obtain a quadratic equation which can be solved easily. However, a graphical solution based on the $y-x$ diagram is usually preferred because it is a visual method that can also be easily applied to nonideal mixtures. The desired concentrations of vapor y and liquid x can be determined from the point of intersection of the operating lines with the equilibrium line. Subsequent total condensation of the vapors is not accompanied by a change in concentration; i.e., the distillate concentration x_D is the same as the vapor concentration y. This is represented graphically in the $y-x$ diagram by the intercept of the horizontal line between $y*$ and x_D (i.e., y is constant) with the diagonal. Figure 8 B clearly shows the large

concentration difference between the heads x_D and the bottoms x_B. The decisive factor here is the position of the equilibrium curve, i.e., for ideal systems, the relative volatility α. Generally, only a limited difference between the concentrations of the two fractions can be obtained by simple continuous distillation.

3.1.2. Continuous Distillation of Multicomponent Mixtures

The calculations for multicomponent systems are identical with those used for binary mixtures. The material balance for the apparatus gives the operating line for each substance *i*:

$$y_i = -\dot{L}/\dot{G} \cdot x_i + \left(1 + \dot{L}/\dot{G}\right) \cdot x_{Fi} \tag{3.5}$$

where x_{Fi} is the mole fraction of *i* in the feed. The phase equilibrium is effectively defined by using the equilibrium constant K_i. Thus,

$$y_i^* = K_i \cdot x_i \tag{3.6}$$

For ideal mixtures, the equilibrium constant K_i is a function only of absolute temperature *T*, which is at first unknown. Combining Equations (3.5) and (3.6) gives the following relationship for each component *i*:

$$y_i = \frac{x_{Fi} \cdot \left(1 + \dot{L}/\dot{G}\right)}{1 + \frac{\dot{L}/\dot{G}}{K_i(T)}} \tag{3.7}$$

From the mole fraction constraint $\sum y_i = 1$,

$$\sum_{i=1}^{k} \frac{x_{Fi} \cdot \left(1 + \dot{L}/\dot{G}\right)}{1 + \frac{\dot{L}/\dot{G}}{K_i(T)}} = 1 \tag{3.8}$$

This set of equations must be solved iteratively. A trial value for the boiling temperature is first assumed, and the equilibrium constant K_i for each component is then determined. The estimation is checked and corrected by using Equation (3.8). The individual summation terms of Equation (3.8) give the vapor concentration y_i of each component involved.

Iterations involving the boiling temperature can be avoided by using the relative volatility α_{ik}, instead of the equilibrium constant K_i. Equation (3.7) is then solved for K_i, the equilibrium constant, as follows:

$$K_i = \frac{\dot{L}/\dot{G}}{x_{Fi}/y_i \cdot \left(1 + \dot{L}/\dot{G}\right) - 1} \tag{3.9}$$

This relationship applies to each component of the mixture; it also applies to the highest boiling substance *k*.

$$K_k = \frac{\dot{L}/\dot{G}}{x_{Fk}/y_k \cdot \left(1 + \dot{L}/\dot{G}\right) - 1} \tag{3.10}$$

Using the relationship $\alpha_{ik} = K_i/K_k$ gives

$$\alpha_{ik} = \frac{x_{Fk}/y_k \cdot \left(1 + \dot{L}/\dot{G}\right) - 1}{x_{Fi}/y_i \cdot \left(1 + \dot{L}/\dot{G}\right) - 1} \tag{3.11}$$

Solving for y_i and employing the mole fraction constant $\sum y_i = 1$ yield

$$\sum_{i=1}^{k} \frac{\alpha_{ik} \cdot x_{Fi} \left(1 + \dot{L}/\dot{G}\right)}{x_{Fk}/y_k \cdot \left(1 + \dot{L}/\dot{G}\right) + \alpha_{ik} - 1} = 1 \tag{3.12}$$

This relationship is equivalent to Equation (3.8) but employs the gas concentration y_k of the highest boiling component as the iteration variable instead of the boiling temperature *T*. Calculation of this method is identical with that of Equation (3.8).

Figure 9. Continuous distillation of a mixture of butane (a), pentane (b), hexane (c), and heptane (d)
x_{Di} = liquid mole fraction of i in distillate; x_{Fi} = liquid mole fraction of i in feed; $\dot{D}$ = distillate stream; $\dot{F}$ = feed stream

Analysis of a quaternary system (a, b, c, d) is illustrated in Figure 9. The ratio of the liquid distillate concentration to the feed concentration

x_{Di}/x_{Fi} (i.e., enrichment) is plotted against the relative amount of distillate $\dot{D}/\dot{F}$. The best separation is achieved at low $\dot{D}/\dot{F}$ values. Obviously separation diminishes as the concentration ratio $\dot{D}/\dot{F}$ approaches unity. Both medium boilers b and c pass through a concentration maximum during distillation.

3.2. Batch Distillation

A schematic of batch distillation is shown in Figure 10. The vapor stream $\dot{G}$ produced by heating L moles of liquid is continuously removed and condensed. The distillate (D) is usually collected in several receivers.

Figure 10. Schematic of batch distillation

3.2.1. Batch Distillation of Binary Mixtures

Material balance around the apparatus permits calculation of the batch distillation of a binary mixture of substances a and b. For a differential time element dt, the following holds:

$$\dot{G} \cdot \mathrm{d}t + \mathrm{d}L = 0 \tag{3.13}$$

and

$$\dot{G} \cdot y \cdot \mathrm{d}t + \mathrm{d}\,(L \cdot x) = 0$$

where the vapor and liquid mole fractions x and y refer to the more volatile component a. By using $\dot{G} = \mathrm{d}G/\mathrm{d}t$, the Rayleigh equation is obtained [26]:

$$\frac{\mathrm{d}L}{L} = \frac{\mathrm{d}x}{y^* - x} \tag{3.14}$$

For ideal mixtures, the equilibrium concentration of a in the vapor phase, $y*$, can be represented by

$$y^* = \frac{\alpha \cdot x}{1 + (\alpha - 1) \cdot x} \tag{3.15}$$

An analytical solution to the differential equation is obtained by substitution into Equation (3.14):

$$\frac{L}{L_0} = \left[\frac{x}{x_0}\right]^{1/(\alpha-1)} \cdot \left[\frac{1-x_0}{1-x}\right]^{\alpha/(\alpha-1)} \tag{3.16}$$

where the subscript 0 represents the liquid in its initial state.

Typical changes in the concentrations of the more volatile component a in the vapor and in the liquid are plotted against the relative amount of distillate $D/L_0 = 1 - L/L_0$ in Figure 11. During the operation, both phases are increasingly depleted of substance a. The intermediate distillate concentration x_{Dm} ($= y_m$) is given by

$$x_{Dm} = x + \frac{x_0 - x}{D/L_0} \tag{3.17}$$

This equation can be interpreted visually with the help of Figure 11. Even for nonideal mixtures, the intermediate distillate concentration x_{Dm} can be determined easily.

Figure 11. Batch distillation of a binary mixture a – b showing concentrations of the more volatile component a in the boiler (x) and in the vapor or distillate (y) as a function of the relative amount of distillate D/L_0
The intermediate distillate concentration x_{Dm} can be determined graphically (see Eq. 3.17).

3.2.2. Batch Distillation of Multicomponent Mixtures

The Rayleigh equation (Eq. 3.14) can be applied directly to multicomponent mixtures. The following holds for each component *i* of a system:

$$\frac{\mathrm{d}L}{L} = \frac{\mathrm{d}x_i}{y_i^* - x_i} \tag{3.18}$$

Numerical methods are generally used to solve this set of equations because the equilibrium concentration $y*_i$ is usually influenced by all the substances present in the mixture.

An analytical solution is obtained under ideal conditions by employing the equilibrium constant $K_i = y*_i/x_i$ which is then independent of the other components of the system. Hence, the following equation applies:

$$\frac{\mathrm{d}L}{L} = \frac{\mathrm{d}x_i}{x_i \cdot (K_i - 1)} \tag{3.19}$$

Rearrangement gives

$$(K_i - 1) \cdot \mathrm{d}\ln L = \mathrm{d}\ln x_i \tag{3.20}$$

Integration of each component gives

$$(K_i - 1) \cdot \ln (L/L_0) = \ln (x_i/x_{i0}) \tag{3.21}$$

where the index 0 denotes the starting condition. Solving for the concentration x_i gives

$$x_i = x_{i0} \cdot (L/L_0)^{K_i^{-1}} \tag{3.22}$$

For the mole fraction constraint $\Sigma x_i = 1$, the following is obtained:

$$\sum_{i=1}^{k} x_{i0} \cdot (L/L_0)^{K_i^{-1}} = 1 \tag{3.23}$$

To solve Equation (3.23) for given L/L_0 values, the boiling temperature of the mixture must be estimated. The vapor pressure of each substance $p^0{}_i$, and consequently the equilibrium constant $K_i = p^0{}_i/p$, can then be determined. The temperature estimation is checked and corrected iteratively by employing the above relationship, whereby convergence is usually attained rapidly.

Alternatively, temperature iteration can be avoided by using the relative volatility α_{ik} instead of the equilibrium constant K_i. By analogy with Equations (3.9) – (3.12):

$$\sum_{i=1}^{k} \left[x_{i0} \cdot (L/L_0)^{\alpha_{ik}-1} \cdot (x_k/x_{k0})^{\alpha_{ik}} \right] = 1 \tag{3.24}$$

In this case, instead of absolute temperature *T*, the mole fraction of the high boiler x_k is the iteration variable. Equations (3.23) and (3.24) describe the changes in concentration of the liquid in the boiler. Thus, the distillate composition can be determined with the help of the equilibrium constant K_i.

Variation of liquid and vapor concentration with the relative amount of distillate D/L_0 for a quaternary mixture is shown in Figure 12. The concentration of the most volatile component (a) decreases first because it is released preferentially into the vapor phase. Concentrations of the higher boiling substances in the boiler consequently increase. When most of substance a is separated ($D/L_0 \approx 0.7$ in Fig. 12), substance b is the most volatile component, so its concentration decreases similarly. Both medium-boiling substances b and c pass through a concentration maximum in the course of distillation. The distillate is collected in several receivers, which enable the recovery of fractions of varying composition. However, complete separation of a liquid mixture into pure components is seldom achieved. Batch rectification must usually be employed for this (see Chap. 5).

Figure 12. Course of concentration changes during the batch distillation of a mixture of butane (a), pentane (b), hexane (c), and heptane (d)
—— Mole fraction of component in the liquid in the boiler, x_i; – – – Mole fraction of component in the distillate, y_i

3.3. Semicontinuous Distillation

Semicontinuous distillation can often be used to advantage with liquids containing small amounts of impurities with low volatility. As shown schematically in Figure 13, feed is fed continuously into the boiler at a rate $\dot{F}$, and head product is withdrawn continuously at a rate $\dot{D}$. During the course of distillation, low-volatility impurities collect in the boiler and must be drained off periodically.

Figure 13. Schematic of semicontinuous distillation

3.3.1. Semicontinuous Distillation of Binary Mixtures

As in Equation (3.14), a material balance for a binary mixture yields

$$\frac{\mathrm{d}F}{L_0} = \frac{\mathrm{d}x}{x_\mathrm{F} - y^*(x)} \tag{3.25}$$

where mole fractions refer to the more volatile component a. For ideal mixtures, integration gives

$$\frac{F}{L_0} = \frac{\alpha - 1}{x_\mathrm{F}(\alpha - 1) - \alpha} \cdot (x - x_\mathrm{F}) - \\ - \frac{\alpha}{[x_\mathrm{F}(\alpha - 1) - \alpha]^2} \cdot \\ \cdot \ln \left\{ \frac{x[x_\mathrm{F}(\alpha - 1) - \alpha] + x_\mathrm{F}}{x_\mathrm{F}[x_\mathrm{F}(\alpha - 1) - \alpha] + x_\mathrm{F}} \right\} \tag{3.26}$$

Hence, the concentration changes of impurities in the boiler and in the distillate can be determined. Variation with time t of the concentration is given in the relationship $F = \dot{F} \cdot t$. In the special case of nonvolatile impurites (i.e., $\alpha \to \infty$), Equation (3.26) is simplified as follows:

$$F/L_0 = \frac{x - x_\mathrm{F}}{x_\mathrm{F} - 1} \tag{3.27}$$

Rearrangement gives

$$x = x_\mathrm{F} + F/L_0 \cdot (x_\mathrm{F} - 1) \tag{3.28}$$

Thus, the concentration x of the more volatile substance in the boiler decreases linearly with the amount of feed, while that of the less volatile substance $(1 - x)$ increases linearly.

3.3.2. Semicontinuous Distillation of Multicomponent Mixtures

In combination with a suitable equilibrium relationship, Equation (3.25) can also be used to describe multicomponent mixtures. In general, a set of differential equations is obtained, which are coupled by means of the equilibrium concentrations. However, this does not apply to ideal mixtures because the equilibrium constant K_i of each component is independent of other substances in the mixture. Individual equations are related to each other only via temperature.

Thus, for ideal solutions,

$$\frac{\mathrm{d}F}{L_0} = \frac{\mathrm{d}x_i}{x_{\mathrm{F}i} - y_i^*} = \frac{\mathrm{d}x_i}{x_{\mathrm{F}i} - K_i \cdot x_i} \tag{3.29}$$

Rearrangement gives

$$\int_{F=0}^{F} \frac{\mathrm{d}F}{L_0} = -\frac{1}{K_i} \int_{x_i = x_{\mathrm{F}i}}^{x_i} \cdot \mathrm{dln}\,(K_i \cdot x_i - x_{\mathrm{F}i}) \tag{3.30}$$

After integration, the following equation is obtained:

$$\frac{F}{L_0} = -\frac{1}{K_i} \cdot \ln \frac{K_i \cdot x_i - x_{\mathrm{F}i}}{x_{\mathrm{F}i} \cdot (K_i - 1)} \tag{3.31}$$

Solving for the concentration of component i and using the mole fraction constraint $\Sigma x_i = 1$ yields

$$\sum_{i=1}^{K} \frac{1}{K_i} \cdot \left[x_{\mathrm{F}i} + x_{\mathrm{F}i} \cdot (K_i - 1) \cdot \exp\left(-\frac{F}{L_0} \cdot K_i \right) \right] = 1 \quad (3.32)$$

This equation can be solved iteratively, the temperature T being the iteration variable. The individual summation terms give the concentrations x_i in the boiler.

4. Continuous Rectification (Multiple Distillation)

4.1. Principles

As discussed in Chapter 3, only limited separation of components is possible in simple distillation. The composition difference between the fractionation products is often very small; therefore, pure substances are seldom obtained.

Figure 14 represents a multiple distillation, i.e., rectification. The overhead product of the first distillation is subjected to a second distillation, whose overhead product, in turn, is subjected to a third distillation and so on. Like Figure 8, the vapor and liquid concentrations at each step can be determined easily on the $y-x$ diagram (Fig. 14 B).

This process can yield a very pure fraction, but it has two serious disadvantages:

1) Only a small part of the starting mixture is recovered in a highly concentrated state.
2) Byproducts are obtained at each stage, which often cannot be processed further.

Both disadvantages can be avoided if the liquid from each distillation step is returned to the previous step, as shown in Figure 15 A. The vapor does not have to be condensed before each step nor does the liquid have to be subsequently revaporized (Fig. 15 B). On the contrary, vapor and liquid can be brought into direct contact. In fact, intensive countercurrent contact between the vapor and liquid streams at each stage is important so that intensive mass transfer can take place. The concentrations attainable at each step can be determined on the $y-x$ diagram by means of material balances around the top of each column, as shown in Figure 16.

Two methods are usually employed to evaluate countercurrent separation efficiency: the equilibrium-stage and the transfer-unit concepts.

4.1.1. Equilibrium-Stage Concept

The equilibrium-stage concept assumes that the vapor and liquid phases are indistinct mass-transfer elements, where they are brought into such intimate contact that they are in equilibrium with each other at each stage. The phases are subsequently separated; vapor flows up to the next stage and liquid runs down to the stage below (countercurrent phase flow), as shown in Figure 16. A material balance for the more volatile component around the top of the column gives the following relationship for the vapor and liquid concentrations (x, y) and streams ($\dot{G}$, $\dot{L}$) between the individual stages:

$$y_{n-1} = \frac{\dot{L}_n}{\dot{G}_{n-1}} \cdot x_n + \frac{\dot{G}_0}{\dot{G}_{n-1}} \cdot y_0 - \frac{\dot{L}_0}{\dot{G}_{n-1}} \cdot x_0 \quad (4.1)$$

The subscripts 0, n, and $n-1$ refer to the stages from which the mass stream originates, 0 being the initial stage. When Equation (4.1) is plotted on the $y-x$ diagram, it furnishes the operating line (Fig. 16 B). The phase equilibrium can also be represented by a line on the $y-x$ diagram. The liquid concentration x_n is connected to the vapor concentration y_{n-1} by a balance line; the concentrations x_n and y_{n-1} define a point on the operating line. Equilibrium exists between y_n, the vapor above stage n, and x_n the liquid concentration in the same stage. Therefore, a vertical line at the liquid concentration x_n must intersect the equilibrium curve at point y_n. Likewise, a horizontal line at the vapor concentration y_n must pass through the point x_{n+1} on the operating line. The point of intersection of x_{n+1} with the equilibrium curve gives the vapor concentration y_{n+1} of the stage above and so on. Alternate use of the equilibrium curve and the operating line to "step" from one equilibrium stage to the other is illustrated on the $y-x$ diagram in Figure 16 B. The operating line is the locus of states between the individual stages.

The number of equilibrium stages n required to achieve a desired concentration change is a good index of the difficulty of separation. The number of equilibrium stages, represented by steps, can easily be determined graphically

Figure 14. Multiple distillation of a binary mixture a – b
A) Flow diagram; B) Determination of vapor and liquid mole fractions of component a at each stage on a y – x diagram

Figure 15. Improvement of multiple distillation by returning liquid from each distillation step to the previous step with (A) or without (B) condensation

Figure 16. Equilibrium-stage concept for determining countercurrent separation efficiency
A) Schematic showing equilibrium stages and associated parameters: dotted – dashed line indicates the boundary for the material balance described in Equation (4.1).
B) McCabe – Thiele diagram: concentrations at each equilibrium stage and number of stages can be determined by stepping off the stages between the equilibrium line and the operating line.

on the $y-x$ diagram; this is often called the McCabe – Thiele method. Analytical solutions are available for a few special cases. A particularly important case occurs when both the equilibrium curve and the operating line are straight lines; the number of equilibrium stages n is given by [27]

$$n = -\frac{1}{\ln \frac{m}{\dot{L}/\dot{G}}} \ln \left[\left(\frac{m}{\dot{L}/\dot{G}} - 1 \right) \frac{y - y_0}{y_0^* - y_0} + 1 \right] \tag{4.2}$$

where m is the slope of the equilibrium line. When $m/(L/G) = 1$,

$$n = -\frac{y - y_0}{y_0^* - y_0} \tag{4.3}$$

Equation (4.2) can often be used to determine the number of stages in the separation of minute impurities.

4.1.2. Transfer-Unit Concept

The concept of transfer units, conceived by Chilton and Colburn, considers a differential transfer area dA of the column [28]. It is illustrated schematically in Figure 17 A. Mass transfer can be formulated as follows:

$$d\dot{N} = K_{\mathrm{OG}} \cdot (y^* - y) \cdot \mathrm{d}A \tag{4.4}$$

where K_{OG} is the overall mass transfer coefficient. The molar mass stream d$\dot{N}$ causes a change in vapor composition dy:

Figure 17. Transfer-unit concept for determining countercurrent separation efficiency
A) Flow diagram showing important parameters and material balance boundaries (I, II)
B) A y – x diagram: the number of transfer units N_{OG} is determined by integrating between the equilibrium line and the operating line (shaded area)

$$\dot{G} \cdot \mathrm{d}y = \mathrm{d}\dot{N} \tag{4.5}$$

Thus,

$$\dot{G} \cdot \mathrm{d}y = K_{OG} \cdot (y^* - y) \cdot \mathrm{d}A \tag{4.6}$$

Separating variables gives

$$\frac{\mathrm{d}y}{y^* - y} = \frac{K_{OG} \cdot \mathrm{d}A}{\dot{G}} \tag{4.7}$$

The term on the right-hand side of Equation (4.7) contains factors pertaining mainly to the apparatus, which are of interest only for column design (see Chap. 8). The difficulty of separation is characterized sufficiently by the term on the left-hand side, which contains factors pertaining mainly to the process itself. It is defined as the overall number of gas-phase transfer units N_{OG}:

$$\mathrm{d}N_{OG} = \frac{\mathrm{d}y}{y^* - y} \tag{4.8}$$

This term can be interpreted as the ratio of the desired concentration change dy to the driving force ($y* - y$) available for mass transfer. At a given liquid state x, y lies on the operating line and $y*$ on the equilibrium curve. The shaded area in Figure 17 B represents the driving force ($y* - y$).

The difficulty of the separation to be accomplished is characterized in terms of transfer units N_{OG}. If N_{OG} is very large a very tall column is required.

The number of transfer units N_{OG} is usually determined by integrating between the operating line and the equilibrium curve, either graphically

or numerically. Analytical solutions are available in a few special cases. Again, the solution when both the equilibrium curve and the operating line are straight lines on the $y-x$ diagram is important [27]:

$$N_{\mathrm{OG}} = -\frac{1}{\frac{m}{\dot{L}/\dot{G}} - 1} \cdot$$

$$\cdot \ln\left[\left(\frac{m}{\dot{L}/\dot{G}} - 1\right) \cdot \frac{y - y_0}{y_0^* - y_0} + 1\right] \tag{4.9}$$

When $m/(L/G) = 1$,

$$N_{\mathrm{OG}} = -\frac{y - y_0}{y_0^* - y_0} \tag{4.10}$$

Equation (4.9) is comparable to Equation (4.2) for the number of equilibrium steps n.

4.1.3. Comparison of Equilibrium-Stage and Transfer-Unit Concepts

The equilibrium-stage concept for characterization of the difficulty of separation provides an adequate measure of separability for distinct mass-transfer elements in countercurrent columns, e.g., in a highly efficient plate column. On the other hand, the transfer-unit concept is preferred when vapor and liquid are in continuous contact, e.g., in packed columns and plate columns which have an efficiency well below 1. The equilibrium-stage concept is used almost exclusively in practice because graphical determination of the number of equilibrium steps on the $y-x$ diagram is much easier than integration with respect to the driving force.

The equilibrium curve and the operating line can almost always be linearized in narrow concentration ranges. The following relationship is then obtained:

$$N_{\mathrm{OG}} = n \cdot \frac{\ln \frac{m}{\dot{L}/\dot{G}}}{\frac{m}{\dot{L}/\dot{G}} - 1} \tag{4.11}$$

In the special case when $m/(\dot{L}/\dot{G}) \to 1, N_{\mathrm{OG}} \approx n$. This condition is often satisfied to a close approximation in difficult separations that require many equilibrium stages or transfer units.

Figure 18. Schematic of a continuously operated rectification column used to separate a binary mixture
Part of the overhead product and part of the bottom product are returned to the column to maintain countercurrent flow. Boundaries for material balances discussed in the text are indicated by dotted – dashed lines (I – IV).

4.2. Rectification of Binary Mixtures

A continuously operated rectification column is shown schematically in Figure 18. The binary feed material (molar flow rate $\dot{F}$) is introduced into the middle of the column. The distillate (molar flow rate $\dot{D}$), which mainly contains the lower boiling component a, is withdrawn from the top of the column. The bottom product (molar flow rate $\dot{B}$), which contains the higher boiling component b in greater concentration, is removed from the bottom of the column. Some overhead and bottom products are returned to the column to maintain countercurrent flow of vapor and liquid in the column. As discussed in Chapter 3, this is a prerequisite for the separation of feed

into substances a and b with maximum purity. The sections of the column above and below the feed are called the *rectification section* and the *stripping section,* respectively.

4.2.1. Prediction of Rectification Based on Material Balance

Rectification can be predicted simply with the help of material balances by assuming that the vapor and liquid streams ($\dot{G}$ and $\dot{L}$, respectively) in the column do not change (see Section 4.2.2).

The overall column balance (boundary I in Fig. 18) yields

$$\dot{F}=\dot{D}+\dot{B}$$
$$\dot{F}\cdot z_{\mathrm{F}}=\dot{D}\cdot x_{\mathrm{D}}+\dot{B}\cdot x_{\mathrm{B}} \tag{4.12}$$

where z_{F}, x_{D}, and x_{B} are the mole fractions of the more volatile substance a in the feed, distillate, and bottom product, respectively. Rearrangement gives

$$\dot{D}=\dot{F}\,\frac{z_{\mathrm{F}}-x_{\mathrm{B}}}{x_{\mathrm{D}}-x_{\mathrm{B}}} \text{ and } \dot{B}=\dot{F}\cdot\frac{x_{\mathrm{D}}-z_{\mathrm{F}}}{x_{\mathrm{D}}-x_{\mathrm{B}}} \tag{4.13}$$

These values can be used to determine the quantities of distillate $\dot{D}$ and bottom product $\dot{B}$ for given product specifications. A material balance for the top of the column (boundary II in Fig. 18) gives a relationship for the states in the column:

$$\dot{G}=\dot{L}+\dot{D}$$
$$\dot{G}\cdot y=\dot{L}\cdot x+\dot{D}\cdot x_{\mathrm{D}} \tag{4.14}$$

where $\dot{L}$ is the molar stream of the reflux liquor returned to the column. Thus,

$$y=\frac{\dot{L}}{\dot{G}}\cdot x+\left(1-\frac{\dot{L}}{\dot{G}}\right)\cdot x_{\mathrm{D}} \tag{4.15}$$

The exact position in the column to which balance II applies is not defined. Hence, Equation (4.15) gives the relationship between the vapor concentration y and the liquid concentration x at any point in the column above the point of feed entry, i.e., in the rectifying section. Because $\dot{L}/\dot{G}$ is constant, Equation (4.15) represents a straight line–the rectifying operating line–with a slope of $\dot{L}/\dot{G}$ on the $y-x$ diagram, which intersects the $y=x$ diagonal at x_{D} (Fig. 19).

Figure 19. McCabe – Thiele diagram for a binary mixture a – b
Shaded area between the operating line and the equilibrium curve is decisive for operation. Equilibrium stages are also shown.
a) Equilibrium line; b) Feed or φ line; c) Rectifying operating line; d) Stripping operating line

The ratio $\dot{L}/\dot{G}$ is known as the *internal reflux ratio.* The use of the *external reflux ratio R* is more advantageous:

$$R=\frac{\dot{L}}{\dot{D}} \tag{4.16}$$

Thus Equation (4.15) becomes

$$y=\frac{R}{R+1}\cdot x+\frac{1}{R+1}\cdot x_{\mathrm{D}} \tag{4.17}$$

Analogously, material balance III around the bottom of the column yields the following relationship:

$$\bar{y}=\frac{\bar{\dot{L}}}{\bar{\dot{G}}}\cdot\bar{x}+\left(1-\frac{\bar{\dot{L}}}{\bar{\dot{G}}}\right)\cdot x_{\mathrm{B}} \tag{4.18}$$

where the horizontal bar ($\bar{y}$, $\bar{x}$, etc.) denotes parameters below the feed point, i.e., in the stripping section. Use of the *external reboil ratio* $\bar{R}$, according to the definition $\bar{R}=\bar{\dot{G}}/\dot{B}\bar{R}=\bar{G}\cdot/\dot{B}$, gives

$$\bar{y}=\frac{\bar{R}+1}{\bar{R}}\cdot\bar{x}-\frac{1}{\bar{R}}\cdot x_{\mathrm{B}} \tag{4.19}$$

Equation (4.19) defines the relationship between the vapor concentration $\bar{y}$ and the liquid concentration $\bar{x}$. If the flow rates $\bar{G}\cdot$ and $\bar{L}\cdot$ are assumed to be constant, it represents a straight line, called

Figure 20. Rectification column and McCabe – Thiele diagram for multiple feed entries or side-stream withdrawal
A) Flow diagram; B) McCabe – Thiele diagram for two feeds; C) McCabe – Thiele diagram for one feed and one side stream

the stripping operating line, on the $y-x$ diagram (Fig. 19). Feed is introduced into the column at the point of intersection of the rectifying and stripping operating lines defined by Equations (4.17) and (4.19) (see Fig. 19). Material balance IV around the feed point gives the following equation for the point of intersection [29]:

$$y=\frac{\varphi}{\varphi-1}\cdot x-\frac{1}{\varphi-1}\cdot z_{\mathrm{F}} \tag{4.20}$$

The caloric factor φ characterizes the thermal condition of the feed and is defined by

$$\varphi=\frac{\text{Enthalpy required to vaporize 1 mol of feed}}{\text{Molar latent heat of vaporization of feed}}$$

If the feed is introduced as a boiling liquid, the value of φ is 1 and Equation (4.20) gives a vertical line on the $y-x$ diagram; i.e., the operating lines intersect at $x=z_{\mathrm{F}}$. However, if the feed is introduced as a saturated vapor, $\varphi=0$ and Equation (4.20) yields a horizontal line; the two operating lines intersect at $y=z_{\mathrm{F}}$. If the feed is introduced into the column as a vapor – liquid mixture, the point of intersection of the two operating lines will be between the two extreme cases described above, as shown in Figure 19. The φ line can also represent a subcooled liquid or a superheated vapor feed.

According to Equation (4.20), the φ line or feed line defines the locus of all points of intersection of the two operating lines in the rectifying and stripping sections of the column. Thus, if the feed conditions and the composition of overhead and bottom products are specified, and one operating line is established, the location of the second operating line is also known. This means

that a relationship exists between the external reflux ratio R and the external reboil ratio $\bar{R}$. If the feed enters at the boiling point, i.e., $\varphi = 1$,

$$\bar{R} = \frac{\dot{D}/\dot{F}}{1-\dot{D}/\dot{F}}(R+1) \tag{4.21}$$

Analogously, for a saturated-vapor feed,

$$\bar{R} = \frac{\dot{D}/\dot{F}}{1-\dot{D}/\dot{F}}(R-1) \tag{4.22}$$

The term $\dot{D}/\dot{F}$ is the relative quantity of overhead product, which can be determined by using Equation (4.13) after the product concentrations have been established.

The calculation of a rectification column with multiple feed entry and side stream withdrawal is conducted in an analogous manner (Fig. 20). The operating line bends at each entry or withdrawal point. Figure 20 B shows the course of the operating lines when $\dot{F}_1$ is a vapor feed stream ($\dot{F}_1 > 0$); Figure 20 C shows the corresponding lines for a vapor side stream ($\dot{F}_1 < 0$).

Figure 21. Enthalpy – concentration diagram of binary mixture a – b
The points of intersection of the lines through poles π_D and π_B with the dew point line and the boiling point line give the concentrations x and y on the operating line.

If the positions of the operating lines and the equilibrium curve on the $y-x$ diagram are known, the difficulty of separation can be determined by using the number of equilibrium stages n (shown as steps in Fig. 19, cf. Section 4.1.1) or the number of transfer units N_{OG} (shaded area in Fig. 19, cf. Section 4.1.2). The desired separation is possible only when the operating lines neither touch nor intersect the equilibrium curve. The smaller the space between the equilibrium curve and the balance lines, the more difficult is the separation.

4.2.2. Prediction of Rectification Based on Material and Enthalpy Balances

The calculation of rectification based on material balance alone is possible only if the vapor and liquid streams ($\dot{G}$ and $\dot{L}$, respectively) in the individual column sections are constant. If this is not the case, the enthalpy balance must also be taken into consideration. The enthalpy – concentration ($h-x$) diagram, shown in Figure 21 for a binary mixture a – b, is very convenient in this respect.

Overall enthalpy balance I (see Fig. 18) for the column gives the following relationship:

$$\dot{F}\cdot h_F + \dot{Q}_R = \dot{D}\cdot h_D + \dot{B}\cdot h_B + \dot{Q}_C \tag{4.23}$$

where h_F, h_D, and h_B are the specific enthalpies of the feed, distillate, and bottom product, respectively; $\dot{Q}_R$ is the molar heat flow supplied by the reboiler; and $\dot{Q}_C$ is the molar heat flow removed by the condenser. Thus,

$$\dot{F}\cdot h_F = \dot{D}\cdot \pi_D + \dot{B}\cdot \pi_B \tag{4.24}$$

where $\pi_D = h_D + \frac{\dot{Q}_C}{\dot{D}}$ and $\pi_B = h_B - \frac{\dot{Q}_R}{\dot{B}}$

Equation (4.24) represents a straight line in Figure 21 that extends from point π_D to point π_B and passes through $\dot{F}$. The amounts of heat $\dot{Q}_R$ and $\dot{Q}_C$ can be determined easily as shown in the diagram when the compositions of the feed and of the desired overhead or bottom products are known (i.e., $\dot{F}$, $\dot{D}$, and $\dot{B}$). Both the distillate ($\dot{D}$) and the bottom product ($\dot{B}$) are assumed to leave the column in the boiling state.

Heat balance II in Figure 18 at the top of the column (rectifying section) gives

$$\dot{G}\cdot h_G = \dot{L}\cdot h_L + \dot{D}\cdot \pi_D \tag{4.25}$$

Here, h_G and h_L are the specific enthalpies of the vapor and liquid, respectively. This equation also represents a straight line through the point π_D on the enthalpy – concentration diagram. If

the vapor in the column is always at the dew point and the liquid always at the boiling point (an assumption that is met closely), the compositions of the vapor $\dot{G}$ and liquid $\dot{L}$ streams as well as their concentrations y and x can be established as shown in Figure 21. Concentrations y and x are points on the operating line on the $y-x$ diagram (Fig. 19). Analogously, if the balance lines in the stripping section are allowed to pass through π_B, the vapor and liquid states are obtained from the points of intersection with the dew point and the boiling point lines, respectively, as shown in Figure 21. The operating lines in the rectifying and stripping sections are obtained by transferring the vapor and liquid concentrations to the $y-x$ diagram. The operating lines are generally slightly curved. The quantities of vapor and liquid can be determined by using the lever arm rule:

$$\dot{G}\cdot l_2=\dot{L}\cdot(l_1+l_2) \text{ or } \frac{\dot{L}}{\dot{G}}=\frac{l_2}{l_1+l_2} \tag{4.26}$$

where l_1 is the distance between the boiling point and dew point lines and l_2 is the distance between the pole π_D and the dew point line.

In the special case in which the dew point line runs parallel to the boiling point line on the enthalpy – concentration diagram, Equation (4.26) produces a constant value for $\dot{L}/\dot{G}$. Thus, the criteria for constant vapor and liquid loads can be formulated:

1) The enthalpies of vaporization of the two substances a and b must be equal.
2) No heat of mixing should occur.
3) The boiling points of the substances should be as close as possible.

The first criterion is the most important. Equal enthalpies of vaporization can often be achieved by using molar enthalpies of vaporization, which in turn require that the composition be given in mole fractions. Thus, rectification calculations generally employ these units.

If the criteria for a constant liquid – vapor ratio $\dot{L}/\dot{G}$ are not satisfied, the following approach is recommended:

1) The poles π_D and π_B are etablished on the enthalpy – concentration diagram.
2) The vapor and liquid concentrations y and x are determined, in each case, by drawing straight lines that radiate from these poles. The values thus obtained are plotted on a McCabe – Thiele diagram and the curved operating line is obtained, point by point.
3) The number of equilibrium steps n or the number of transfer units N_{OG} is determined in the usual manner on the $y-x$ diagram.

The number of equilibrium steps can also be determined on the $h-x$ diagram [30], but this method is so complex that it has little practical use.

4.2.3. Rectification of Binary Mixtures at Infinite Reflux Ratio

If the internal streams $\dot{G}$ and $\dot{L}$ are much larger than those of the feed ($\dot{F}$) and the products ($\dot{D}$ and $\dot{B}$), the internal reflux ratio $\dot{L}/\dot{G}$ in all parts of the column approaches 1. Thus, according to Equations (4.15) and (4.17),

$$R\rightarrow\infty \tag{4.27}$$

In this special case (i.e., at infinite reflux ratio), the energy input needed for separation is very large, but a minimum number of equilibrium stages n or transfer units N_{OG} is required. As shown in Figure 22, the operating line coincides with the diagonal and is represented by the simple equation

$$y=x \tag{4.28}$$

The equilibrium state $y*$ is determined by starting with the liquid state x_B. The new liquid concentration x_1 is now calculated from the vapor concentration according to Equation (4.28). The vapor state y_1* in equilibrium with this liquid concentration x_1 is, in turn, determined and so on. This procedure is identical with the determination of the distillation curve described in Section 2.2.3. Equation (2.25) thus applies to ideal binary mixtures with constant relative volatility α:

$$x_D=\frac{\alpha^n\cdot x_B}{1+(\alpha^n-1)\cdot x_B} \tag{4.29}$$

After rearrangement, the minimum number of equilibrium steps n_{min} is obtained:

$$n_{min}=\frac{1}{\ln\alpha}\cdot\ln\left(\frac{x_D}{x_B}\cdot\frac{1-x_B}{1-x_D}\right) \tag{4.30}$$

Analogously, the minimum number of transfer units $N_{\mathrm{OG,\,min}}$ is given by

$$N_{\mathrm{OG,min}} = \frac{1}{\alpha - 1} \cdot \ln \left[\frac{x_{\mathrm{D}}}{x_{\mathrm{B}}} \cdot \left(\frac{1 - x_{\mathrm{B}}}{1 - x_{\mathrm{D}}} \right)^{\alpha} \right] \tag{4.31}$$

Figure 22. McCabe – Thiele diagram of a binary mixture at infinite reflux ratio

4.2.4. Rectification of Binary Mixtures at Minimum Reflux Ratio

Operation with minimum column loads (i.e., minimum reflux ratio) has considerable practical importance because it results in separation of a mixture by using the smallest possible column diameter and the lowest energy input.

Operation with minimal internal loads is characterized by intersection of the rectifying and stripping operating lines at a single point on the equilibrium curve. This point is called a *pinch point,* and an infinite number of equilibrium stages n or transfer units N_{OG} is required to reach this state. Figure 23 shows the $y-x$ diagram for a binary system with minimal internal loads. If the vapor and liquid flow rates ($\dot{G}$ and $\dot{L}$, respectively) in the individual sections of the column are constant, the operating lines are straight lines. The minimum slope of the rectifying operating line for the more volatile component a can be calculated as follows:

$$\left(\frac{\dot{L}}{\dot{G}} \right)_{\min} = \frac{x_{\mathrm{D}} - y_{\mathrm{F}}^{*}}{x_{\mathrm{D}} - x_{\mathrm{F}}^{*}} \tag{4.32}$$

By use of the relationship $\dot{L}/\dot{G} = R/(R+1)$, the minimum reflux ratio becomes

$$R_{\min} = \frac{x_{\mathrm{D}} - y_{\mathrm{F}}^{*}}{y_{\mathrm{F}}^{*} - x_{\mathrm{F}}^{*}} \tag{4.33}$$

Concentrations $y*_{\mathrm{F}}$ and $x*_{\mathrm{F}}$ are related by the phase equilibrium. By using Equation (2.17), the following relationship is obtained for ideal mixtures:

$$R_{\min} = \frac{1}{\alpha - 1} \left(\frac{x_{\mathrm{D}}}{x_{\mathrm{F}}^{*}} - \alpha \frac{1 - x_{\mathrm{D}}}{1 - x_{\mathrm{F}}^{*}} \right) \tag{4.34}$$

If the overhead product is required as pure substance a (i.e., $x_{\mathrm{D}} = 1$), Equation (4.34) can be simplified:

$$R_{\min} = \frac{1}{(\alpha - 1) \cdot x_{\mathrm{F}}^{*}} \tag{4.35}$$

The point of intersection of the feed line (Eq. 4.20) with the equilibrium line (Eq. 2.17) gives the concentration $x*_{\mathrm{F}}$. A quadratic equation is obtained which can be solved as follows:

$$x_{\mathrm{F}}^{*} = -\frac{B}{2} + \sqrt{\frac{B^2}{4} + C} \tag{4.36}$$

where

$$B = \frac{1}{\varphi} \left(\frac{\alpha}{\alpha - 1} - \varphi - z_{\mathrm{F}} \right)$$

$$C = \frac{z_{\mathrm{F}}}{\varphi \cdot (\alpha - 1)}$$

z_{F} is the mole fraction of substance a in a liquid – vapor feed and φ is the thermal state of the feed (caloric factor) defined in section 4.2.1.

Figure 23. McCabe – Thiele diagram of a binary mixture at minimum reflux ratio and minimum reboil ratio
The operating lines intersect the equilibrium line at the pinch point.

If the feed is a boiling liquid with composition x_F, then

$$x_F^* = x_F \tag{4.37}$$

If the feed is a saturated vapor with composition y_F, then

$$x_F^* = \frac{y_F/\alpha}{1-(\alpha-1)\,y_F/\alpha} \tag{4.38}$$

Analogously, laws can be derived for the minimum reboil ratio $\bar{R} = \dot{\bar{G}}/\dot{B}$. The slope of the stripping operating line can be calculated by using Figure 23 as follows:

$$\left(\frac{\dot{L}}{\dot{\bar{G}}}\right)_{max} = \frac{y_F^* - x_B}{x_F^* - x_B} \tag{4.39}$$

From the relationship $\dot{\bar{L}}/\dot{\bar{G}} = \left(\bar{R}+1\right)/\bar{R}$, the minimum reboil ratio is

$$\bar{R}_{min} = \frac{x_F^* - x_B}{y_F^* - x_F^*} \tag{4.40}$$

The relationship $y*_F = f(x*_F)$ can be formulated easily for ideal mixtures:

$$\bar{R}_{min} = \left[\frac{1}{1-x_B/x_F^*}\cdot\left(\frac{\alpha}{1+(\alpha-1)\cdot x_F^*}-1\right)\right]^{-1} \tag{4.41}$$

An important case exists when pure substance b is to be separated as the bottom product (i.e., $x_{B_a} = 0$):

$$\bar{R}_{min} = \left[\frac{\alpha}{1+(\alpha-1)\cdot x_F^*}-1\right]^{-1} \tag{4.42}$$

The concentration $x*_F$ can generally be calculated from the composition z_F and the thermal state φ of the feed (Eq. 4.36). Again, the special cases in which the feed is a boiling liquid or a saturated vapor are very important. The relationship between the minimum reflux ratio and the minimum reboil ratio can then be expressed by using Equations (4.21) and (4.22). Separation using a rectification column with a minimum reflux ratio requires an infinite number of equilibrium steps n or transfer units N_{OG}. However, even a slight increase in the reflux ratio of ca. 5 – 10 % can result in economical operation. Thus, the special case and laws discussed in this section closely approximate actual rectification and have immediate practical importance.

4.2.5. Heat Requirements for Rectification of Binary Mixtures

In rectification columns, a quantity of heat $\dot{Q}_R$ is supplied in the reboiler at the bottom of the column and a quantity $\dot{Q}_C$ is removed by the condenser at the top. The following equations hold:

$$\dot{Q}_R = r\cdot\dot{G} \; or \; \dot{Q}_C = -\,r\cdot\dot{G} \tag{4.43}$$

where r is the molar latent heat of vaporization for the substance in question. Approximately equal molar heats of vaporization of the substances involved are assumed.

Important relationships can be established for the quantities of heat $\dot{Q}_R$ and $\dot{Q}_C$. The heat required by the reboiler $\dot{Q}_R$ is formulated by using the reboil ratio $\bar{R} = \dot{\bar{G}}/\dot{B}$. The heat removed by the condenser $\dot{Q}_C$ is determined by using the reflux ratio $R = \dot{L}/\dot{D}$. Thus,

$$\dot{Q}_R = r\cdot\bar{R}\cdot\dot{B} \text{ or } \dot{Q}_C = -r\cdot(R+1)\cdot\dot{D} \tag{4.44}$$

The term $(R+1)$ arises because both the reflux liquid and the overhead product must be condensed at the top of the column.

The product flow rates $\dot{B}$ and $\dot{D}$ in binary mixtures can be expressed in terms of the feed stream $\dot{F}$ and the composition of the products by using Equation (4.13).

$$\frac{\dot{Q}_R}{\dot{F}\cdot r} = \bar{R}\cdot\frac{x_D - z_F}{x_D - x_B}$$

and

$$\frac{\dot{Q}_C}{\dot{F}\cdot r} = -\,(R+1)\cdot\frac{z_F - x_B}{x_D - x_B} \tag{4.45}$$

Thus, $\dot{Q}_R$ and $\dot{Q}_C$ are directly proportional to the reboil ratio $\bar{R}$ and the reflux ratio R, respectively. These ratios cannot fall below a limiting value (for details, see Section 4.2.4); the minimal quantities of heat are calculated as follows:

$$\frac{\dot{Q}_{R,min}}{\dot{F}\cdot r} = \bar{R}_{min}\cdot\frac{x_D - z_F}{x_D - x_B}$$

$$\frac{\dot{Q}_{C,min}}{\dot{F}\cdot r} = -\,(R_{min}+1)\cdot\frac{z_F - x_B}{x_D - x_B} \tag{4.46}$$

If fractionation into a pure product a is required during rectification of a binary mixture (i.e.,

Figure 24. Separation of an ideal ternary mixture a – b – c in a single rectification column
A) Triangular phase diagram showing calculated distillation curvesEquilibrium stages are shown as open circles on one of the curves. Compositions of the overhead and bottom products $\dot{D}$ and $\dot{B}$ lie on a straight line that passes through the feed $\dot{F}$ and must be located within the shaded areas
B) Schematic of rectification column

$x_{Da} = 1$ and $x_{Ba} = 0$), use of the appropriate relationships for the reboil and reflux ratios gives

$$\frac{\dot{Q}_{R,min}}{\dot{F}\cdot r} = \frac{1}{\alpha - 1}\left(1+\alpha\frac{x_F^*}{1-x_F^*}\right)\cdot(1-z_F)$$

$$\frac{\dot{Q}_{C,min}}{\dot{F}\cdot r} = -\,z_F\left[\frac{1}{(\alpha-1)\cdot x_F^*}+1\right] \tag{4.47}$$

The concentration x_F* can be determined from the concentration of the feed by using Equation (4.36). In the special case of a boiling-liquid feed having composition x_F, the following equations are obtained:

$$\frac{\dot{Q}_{R,min}}{\dot{F}\cdot r} = \frac{1}{\alpha - 1} + x_F \text{ and}$$

$$\frac{\dot{Q}_{C,min}}{\dot{F}\cdot r} = -\left(\frac{1}{\alpha-1}+x_F\right) \tag{4.48}$$

The heat requirement $\dot{Q}_{R,min}$ consists of two terms. The first term accounts for the heat required to maintain the countercurrent in the column and is independent of feed composition. The second term, however, is directly proportional to the composition of the feed and represents the heat required for vaporization of the overhead product; this quantity of heat would also be required for simple distillation.

For a saturated-vapor feed of composition y_F, Equation (4.47) becomes

$$\frac{\dot{Q}_{R,min}}{\dot{F}\cdot r} = \frac{1}{\alpha - 1} \text{ and } \frac{\dot{Q}_{C,min}}{\dot{F}\cdot r} = \frac{1}{\alpha - 1} + 1 \tag{4.49}$$

Both enthalpies are independent of the composition of the feed. If the distillate is withdrawn in the liquid state, more heat must of course be removed from the top of the column than supplied at the bottom.

In general, either the quantity of heat $\dot{Q}_R$ to be added or the quantity of heat $\dot{Q}_C$ to be removed is determined by using the above equations. The remaining quantity of heat is established by using an enthalpy balance around the column. This enthalpy balance can be carried out especially well on the enthalpy – concentration diagram in Figure 21.

If the feed is introduced in the boiling state and the distillate and bottom products are removed in the boiling state, then the following equation holds:

$$\dot{Q}_R \approx -\dot{Q}_C \tag{4.50}$$

This relationship is fully valid only when the boiling point line on the enthalpy – concentration diagram, on which points $\dot{F}$, $\dot{B}$, and $\dot{D}$ are

located, is a straight line. The latent heats of vaporization of components a and b, r_a and r_b, do not have to be equal in this case.

4.3. Rectification of Ternary Mixtures

The binary mixtures discussed in Section 4.2 represent a special case in rectification. Generally, multicomponent mixtures are separated. Rectification of a ternary mixture of substances a, b, and c can be represented relatively clearly on a triangular diagram. Relationships derived from ternary mixtures can be applied directly to multicomponent mixtures.

4.3.1. Rectification of Ternary Mixtures at Infinite Reflux Ratio

A very simple approach to ternary rectification is possible when the internal mass vapor and liquid streams in the column, $\dot{G}$ and $\dot{L}$, are much larger than the feed and product streams $\dot{F}$, $\dot{D}$, and $\dot{B}$ (i.e., $R \to \infty$). For the special case $R \to \infty$, the operating line coincides with the diagonal on the $y-x$ diagram, which means that the vapor concentration y of a given component is always equal to the liquid concentration x. As described in Section 4.2.3, the distillation curve represents the changes in concentration in the column. Thus for ideal mixtures, Equation (2.26) gives the course of concentration changes:

$$x_{na} = \frac{\alpha_{ac}^{n} \cdot x_{Ba}}{1 + (\alpha_{ac}^{n} - 1) \cdot x_{Ba} + (\alpha_{bc}^{n} - 1) \cdot x_{Bb}} \tag{4.51}$$

$$x_{nb} = \frac{\alpha_{bc}^{n} \cdot x_{Bb}}{1 + (\alpha_{ac}^{n} - 1) \cdot x_{Ba} + (\alpha_{bc}^{n} - 1) \cdot x_{Bb}}$$

$$x_{nc} = 1 - x_{an} - x_{bn}$$

where the subscripts a, b, and c denote the three components of the mixture; n denotes the number of equilibrium stages; and B, the bottom product. Starting with a defined liquid composition (e.g., the bottom state $\dot{B}$), the changes in concentration in the column can be calculated as a function of the number of equilibrium stages n. These are represented by the distillation curves shown in Figure 24 A. The arrows indicate the direction in which the boiling temperatures decrease, i.e., toward the top of the column.

A material balance around the column (Fig. 24 B) gives

$$\dot{F} = \dot{D} + \dot{B} \tag{4.52}$$

$$\dot{F} \cdot z_{Fa} = \dot{D} \cdot x_{Da} + \dot{B} \cdot x_{Ba}$$

$$\dot{F} \cdot z_{Fb} = \dot{D} \cdot x_{Db} + \dot{B} \cdot x_{Bb}$$

These equations produce a straight line through the feed $\dot{F}$ on the triangular diagram, which also passes through the points representing the distillate $\dot{D}$ and the bottom product $\dot{B}$.

Figure 25. Separation of a ternary mixture with two minimum azeotropes (p = 101.3 kPa)
Azeotropic points are represented by open circles. The bold line is a distillation boundary which cannot be crossed and divides the phase diagram into two sectors. Shading denotes the separation areas for two different feed compositions F1 and F2.

Both Equations (4.51) and (4.52) must be valid at the ends of the column. Thus, the states of products $\dot{D}$ and $\dot{B}$ must lie both on the balance line through $\dot{F}$ and on a distillation curve. As shown in Figure 24 A, the balance line forms a chord of the distillation curve. Equations (4.51) and (4.52) obviously permit an infinite number of different overhead $\dot{D}$ and bottom $\dot{B}$ products. Limits for $\dot{D}$ and $\dot{B}$ are reached when either pure substance a or pure substance c is obtained at the top or bottom of the column, respectively. All other solutions of Equations (4.51) and (4.52) lie within these extremes; thus, the overhead and bottom products ($\dot{D}$ and $\dot{B}$, respectively) can be

located only in the shaded areas shown on Figure 24 A. This is generally applicable irrespective of the number of equilibrium stages and the mode of operation, i.e., also at a finite reflux ratio R. Thus, a ternary mixture can be separated in a single rectification column to only a very limited extent. Medium-boiling substance b can be recovered in the pure state as a side-stream product only in the special case when $R \to \infty$ and $n \to \infty$; generally it can merely be made more concentrated. Only substances at which distillation curves either start or end can be separated efficiently (see Chap. 6).

Distillation curves for a highly nonideal mixture which forms two binary minimum azeotropes are shown in Figure 25. Shaded regions represent possible separation areas for two different feeds $\dot{F}1$ and $\dot{F}2$. Two sectors exist in which separation into $\dot{D}$ and $\dot{B}$ products occurs. The distillation boundary separating these two sectors connects the two minimum azeotropes and cannot be crossed during rectification. Thus the distillation boundaries of ternary mixtures are as important as the azeotropic points of binary mixtures.

Figure 26. Separation areas of a ternary mixture with three binary azeotropes and one ternary azeotrope

An extreme example of a ternary mixture is shown in Figure 26. The mixture forms three binary azeotropes and one saddle-point ternary azeotrope. Two distillation boundaries exist: one connects the two minimum azeotropes, and the other runs from the high boiler c to the maximum binary azeotrope; they intersect at the saddle point. Hence, the three-component mixture is divided into four distillation fields. Because separation boundaries cannot be crossed during rectification, fractionation is possible only within one field. As illustrated in Figure 26, within a given distillation area, only limited separation is possible.

A knowledge of the paths of distillation curves and the possible positions of distillation boundaries of ternary mixtures is valuable for process design. Details about expected rectification fractions can then be given without extensive column calculation (see Chap. 6). Exact knowledge of the phase equilibrium is not absolutely necessary. The course of the distillation curves and of the separation boundaries can be estimated solely from the boiling temperatures of the marked points, i.e., of the pure substances and the azeotropes.

4.3.2. Rectification of Ternary Mixtures at Minimum Internal Loads

Industrial rectification columns are preferentially operated at a low reflux ratio R. Hence, the special case of the minimum reflux ratio $R_{\min}$ is of considerable interest. A method described in [31] permits determination of the corresponding minimum reflux ratio for any overhead product at a given feed composition. However, the equations can only be solved iteratively. This section shows that the minimum reflux ratio can be calculated directly, i.e., without iteration, in three special cases. Many separations are possible but this method yields an especially favorable, "preferred" separation.

4.3.2.1. Minimum Reflux Ratio and Minimum Reboil Ratio for Preferred Separation

The relationships presented in Section 4.2.4 for the minimum reflux ratio of binary mixtures can be applied directly to ternary mixtures. Hence, as in Equation (4.33), the following is valid for each component i:

$$R_{\min} = \frac{x_{\mathrm{D}i} - y^*_{\mathrm{F}i}}{y^*_{\mathrm{F}i} - x^*_{\mathrm{F}i}} \tag{4.53}$$

This equation represents a straight line through $\dot{F}$, as shown in Figure 27. The minimum reflux ratio for all compositions of the distillate $\dot{D}$ on this line can be determined by using Equation (4.53).

Figure 27. Preferred separation of a ternary mixture at minimum reflux ratio (p = 101.3 kPa)
Both separation products $\dot{D}$ and $\dot{B}$ can lie only on the line through x_{Fi} and $y*_{Fi}$ (feed at boiling point). Thus, only one "preferred" separation exists in the shaded separation area.

If complete removal of the high-boiling substance c from the overhead product is required, then $x_{Dc} = 0$. Thus,

$$R_{min} = -\frac{y^*_{Fc}}{y^*_{Fc} - x^*_{Fc}} \tag{4.54}$$

Concentrations of the other two substances in the distillate can be calculated from Equation (4.53):

$$x_{Da} = (R_{min}+1) \cdot y^*_{Fa} - R_{min} \cdot x^*_{Fa}$$
$$x_{Db} = (R_{min}+1) \cdot y^*Fb - R_{min} \cdot x^*_{Fb} \tag{4.55}$$

These relationships are generally applicable; i.e., they also apply to nonideal mixtures as long as the corresponding straight lines do not intersect the equilibrium curve above the feed point.

For ideal mixtures, the relationship between $y*Fi$ and $x*Fi$ can be formulated in general terms and inserted into Equation (4.54) to give

$$R_{min} = \frac{1}{(\alpha_{ac}-1) \cdot x^*_{Fa} + (\alpha_{bc}-1) \cdot x^*_{Fb}} \tag{4.56}$$

The composition of the head product $\dot{D}$ can then be expressed as:

$$x_{Da} = \frac{(\alpha_{ac}-1) \cdot x^*_{Fa}}{(\alpha_{ac}-1) \cdot x^*_{Fa} + (\alpha_{bc}-1) \cdot x^*_{Fb}} \tag{4.57}$$
$$x_{Db} = \frac{(\alpha_{ac}-1) \cdot x^*_{Fb}}{(\alpha_{ac}-1) \cdot x^*_{Fa} + (\alpha_{bc}-1) \cdot x^*_{Fb}}$$
$$x_{Dc} = 0$$

An analogous equation can be obtained for the minimum reboil ratio:

$$\bar{R}_{min} = \left[\frac{\alpha_{ac}}{1 + (\alpha_{ac}-1) \cdot x^*_{Fa} + (\alpha_{bc}-1) \cdot x^*_{Fb}} - 1\right]^{-1} \tag{4.58}$$

The corresponding composition of the bottom product is given by

$$x_{Ba} = 0 \tag{4.59}$$
$$x_{Bb} = \frac{x^*_{Fb} \cdot (\alpha_{ac} - \alpha_{bc})}{\alpha_{ac} - \left[1 + (\alpha_{ac}-1) \cdot x^*_{Fa} + (\alpha_{bc}-1) \cdot x^*_{Fb}\right]}$$
$$x_{Bc} = \frac{x^*_{Fc} \cdot (\alpha_{ac}-1)}{\alpha_{ac} - \left[1 + (\alpha_{ac}-1) \cdot x^*_{Fa} + (\alpha_{bc}-1) \cdot x^*_{Fb}\right]}$$

Concentrations $x*_{Fi}$ can be determined from the point of intersection of the feed with the equilibrium relationship, as in Section 4.2.4.

Figure 28. Course of the concentration changes in a column for the "preferred" separation of a ternary mixture at minimum reflux ratio (p = 101.3 kPa)
Two different separations are shown. A pinch point is attained in both column sections at the feed composition for the "preferred" separation. This separation is totally analogous to binary rectification at minimum reflux ratio.
—— Balance around the column; –○– Changes in liquid concentration in the column

In the especially important case of a boiling-liquid feed with composition $x_{\mathrm{F}i}$, the following holds:

$$x^*_{\mathrm{F}i} = x_{\mathrm{F}i} \tag{4.60}$$

Introduction of a saturated-vapor feed with composition $y_{\mathrm{F}i}$ represents another important case. Here,

$$x^*_{\mathrm{F}i} = \frac{y_{\mathrm{F}i}/\alpha_{ik}}{1 - \sum\left(\alpha_{jk} - 1\right) \cdot y_{\mathrm{F}j}/\alpha_{jk}} \tag{4.61}$$

The material balance around the column also gives a straight line through the feed point $\dot{F}$. Both products $\dot{D}$ and $\dot{B}$ must be located on this line. Consequently, the bottom state $\dot{B}$ also lies on the straight line established by Equation (4.53). The relative quantities of the overhead product $\dot{D}/\dot{F}$ and of the bottom product $\dot{B}/\dot{F}$ can be calculated by using the lever arm rule.

The changes in concentration within the column obtained at $R_{\min}$ are shown in Figure 28. Case 1 represents a very sharp separation into two fractions $\dot{D}_1$ and $\dot{B}_1$ in which the concentrations of the high boiler in the distillate x_{Dc} and the low boiler in the bottoms x_{Ba} are zero (Eq. 4.54). Case 2 represents a moderate separation of the same feed, also at minimum (still lower) reflux ratio. The concentration changes in both the stripping and the rectification sections lead to, and end at, the feed composition. Thus, the point of intersection of the operating lines with the equilibrium curve (pinch point) coincides with the feed. Equation (4.53) (i.e., the straight line in Fig. 27) represents a certain natural, preferred course of separation, which is achieved with a minimum energy input in an infinitely long rectification column. Here, the reflux ratio $R_{\min}$ has the lowest value. Of the large number of separations possible, separation of the feed into an overhead product $\dot{D}$ and a bottom product $\dot{B}$ at this value represents a very important case. This separation usually lies in the middle of the fractionation region, as shown in Figure 27. This preferred position for the overhead and bottom fractions of a rectification column is extremely important. As described in Chapter 7, it is usually the most favorable separation path for multicomponent rectification.

4.3.2.2. Minimum Reflux Ratio for Separation of the Low Boiler

Often, the most volatile substance of a ternary mixture must be separated from the other components in as pure a state as possible. The minimum reflux ratio can also be calculated directly. In the separation of a "c-free" overhead product, only a binary mixture of substances a and b is present in the upper part of the column (Fig. 28). Enrichment in the high-boiling substance c occurs only when the liquid equilibrium concentration $x*_{\mathrm{a}}$ is reached. The $y-x$ diagram (Fig. 29) plotted in terms of the low boiler (a) clearly indicates the importance of the concentration $x*_{\mathrm{a}}$. The operating line intersects the equilibrium curve, represented by the relative volatility α_{ab}, at the point $x*_{\mathrm{a}}$. Thus, enrichment in the high-boiling component c occurs only after the binary mixture in the column reaches the pinch point. Equation (4.34) can be modified for this state as follows:

$$R_{\min} = \frac{1}{(\alpha_{\mathrm{ab}} - 1)}\left[\frac{x_{\mathrm{Da}}}{x^*_{\mathrm{a}}} - \alpha_{\mathrm{ab}}\frac{1 - x_{\mathrm{Da}}}{1 - x^*_{\mathrm{a}}}\right] \tag{4.62}$$

Figure 29. Derivation of $R_{\mathrm{a,\,min}}$, the minimum reflux ratio for the separation of pure overhead product a from the ternary mixture a – b – c
α_{ab} = relative volatility of a and b; $R_{\min}$ = minimum reflux ratio required for the preferred separation (Eq. 4.34).

If the desired overhead product is pure substance a, then a larger reflux ratio $R_{\mathrm{a,\,min}}$ is required, as illustrated in Figure 29. The new operating line also intersects the binary equilibrium curve at $x*_{\mathrm{a}}$. Since $x_{\mathrm{Da}} = 1$, Equation (4.62) becomes

$$R_{\mathrm{a,min}} = \frac{1}{(\alpha_{\mathrm{ab}} - 1)\cdot x_{\mathrm{a}}^{*}} \tag{4.63}$$

This equation can be solved for $x*_{\mathrm{a}}$ and inserted into Equation (4.62). A quadratic equation is obtained for $R_{\mathrm{a,\,min}}$ which is solved in the following way:

$$R_{\mathrm{a,min}} = -\frac{B}{2} + \sqrt{\frac{B^2}{4} - C}$$

$$\text{where } B = 1 - \frac{1}{x_{\mathrm{Da}}}\left(R_{\mathrm{min}} + \frac{\alpha_{\mathrm{ab}}}{\alpha_{\mathrm{ab}} - 1}\right) \tag{4.64}$$

$$C = \frac{R_{\mathrm{min}}}{(\alpha_{\mathrm{ab}} - 1)\cdot x_{\mathrm{Da}}}$$

The values of R_{min} and x_{Da} are determined by using Equations (4.56) and (4.57). The minimum reflux ratio $R_{\mathrm{a,\,min}}$ required for separation of pure substance a as the overhead product is always larger than the reflux ratio R_{min} for the preferred separation described in Section 4.3.2.1.

Figure 30. Separation of the low boiler (a) from ternary mixture a – b – c as an overhead product at minimum reflux ratio (p = 101.3 kPa)
The pinch point is located directly below the feed point.
—— Balance around the column; –o– Changes in liquid concentration in the column; – · – · – Mixing line at the feed point

The course of concentration changes in the column during separation of the low boiler a are shown in Figure 30. Again, a binary mixture of substances a and b is present in the rectifying part of the column. Enrichment in the high boiler c occurs only at the binary pinch point $x*_{\mathrm{a}}$. The concentration changes in the rectifying section lead to the feed. However, a ternary pinch point is not attained here. The pinch point of the ternary mixture lies in the stripping section of the column at $\dot{\bar{L}}$, i.e., directly below the feed point.

4.3.2.3. Minimum Reboil Ratio for Separation of the High Boiler

An approach similar to that described in Section 4.3.2.2 can be used in the separation of pure bottom product from a ternary mixture. The minimum reboil ratio $\bar{R}$ can be determined according to the definition $\bar{R} = \dot{\bar{G}}/\dot{B}$. The minimum reflux ratio R can then be calculated by using Equation (4.21). The following is analogous to Equation (4.64), where $\bar{R}_{\mathrm{c,\,min}}$ is the minimum reboil ratio required for separation of the high boiler c as a pure bottom product.

$$\bar{R}_{\mathrm{c,min}} = \left(-\frac{B}{2} - \sqrt{\frac{B^2}{4} - C}\right)^{-1} \tag{4.65}$$

where

$$B = -\frac{1}{\bar{R}_{\mathrm{min}}}\left[1 + x_{\mathrm{Bb}}\,(\alpha_{\mathrm{bc}} - 1)\right] - (\alpha_{\mathrm{bc}} - 1)$$

$$C = \frac{(1 - x_{\mathrm{Bb}})\cdot(\alpha_{\mathrm{bc}} - 1)}{\bar{R}_{\mathrm{min}}}$$

In this case, $\bar{R}_{\mathrm{min}}$ is the minimum reboil ratio for the preferred separation according to Equation (4.58). The value x_{Bb} is determined by use of Equation (4.59).

Thus, $\bar{R}_{\mathrm{c,\,min}}$ for the separation of a pure bottom product consisting of the high boiler c can then be determined. The quantities $x*_{\mathrm{F}i}$ are calculated from Equations (4.60) and (4.61), depending on the feed condition. The minimum reboil ratio $\bar{R}_{\mathrm{c,\,min}}$ for separation of pure high boiler c is always larger than the minimum reboil ratio $\bar{R}_{\mathrm{min}}$ required for the preferred separation according to Equation (4.58).

Figure 31 shows the concentration profiles in the column during separation of the high boiler c. The concentrations in the stripping section lead to, but do not end at, the feed. The ternary pinch point, represented by an arrow, lies directly above the feed point.

Figure 31. Separation of the high boiler (c) from ternary mixture a – b – c as bottom product (p = 101.3 kPa) at minimum reflux ratio
The pinch point is located directly above the feed point.
—— Balance around the column; –○– Changes in liquid concentration in the column; – · – · – Mixing line

4.3.3. Rectification of Ternary Mixtures at Finite Reflux Ratio

Rectification at a finite reflux ratio can be calculated by first specifying the column and operating conditions and then determining concentrations at the top and bottom of the column. If the required product specifications are not achieved, either the operating conditions or the column configuration must be altered and the calculation repeated.

The number of equilibrium steps n and the position of the feed entry point are required for column specification. The operating conditions are characterized sufficiently by the reflux ratio R and the relative amount of overhead product $\dot{D}/\dot{F}$. The calculation is best carried out in an analogous manner to the stepwise method used for binary mixtures described in Section 4.1.1 (McCabe – Thiele diagram). By starting with a known liquid composition (e.g., at the bottom), the equilibrium vapor-phase state is calculated. For ideal mixtures,

$$\begin{aligned} y_a^* &= \frac{\alpha_{ac} \cdot x_a}{1 + (\alpha_{ac} - 1) \cdot x_a + (\alpha_{bc} - 1) \cdot x_b} \\ y_b^* &= \frac{\alpha_{bc} \cdot x_b}{1 + (\alpha_{ac} - 1) \cdot x_a + (\alpha_{bc} - 1) \cdot x_b} \\ y_c^* &= 1 - y_a - y_b \end{aligned} \tag{4.66}$$

For nonideal mixtures, the equilibrium state can be determined as described in Chapter 2.

The next step involves elucidation of the new liquid state from the vapor state by using the operating line. Material balance around the bottom of the column gives the following equation for the operating line:

$$\begin{aligned} x_a &= \frac{\bar{R}}{\bar{R}+1} \cdot y_a^* + \frac{1}{\bar{R}+1} \cdot x_{Ba} \\ x_b &= \frac{\bar{R}}{\bar{R}+1} \cdot y_b^* + \frac{1}{\bar{R}+1} \cdot x_{Bb} \\ x_c &= 1 - x_a - x_b \end{aligned} \tag{4.67}$$

Figure 32. Separation of a ternary mixture at a finite reflux ratio (p = 101.3 kPa)
A concentration jump occurs at the feed point due to admixing of feed.
—— Balance around the column; –○– Changes in liquid concentration in the column; – · – · – Mixing line

The alternate use of Equations (4.66) and (4.67) produces a mathematical stepwise construction similar to the graphical construction for binary mixtures on the $y-x$ diagram (see chapter 4). In Figure 32, the concentration changes observed in the stripping section of the column are represented by dots.

When the feed point has been reached, admixing of the feed must be considered in the calculation process. The following relationship is obtained from a material balance for the liquid composition directly above the feed point by assuming a boiling-liquid feed and negligible temperature differences at the feed entry point:

$$x_{\mathrm{a}}=\frac{(\bar{R}+1)\cdot\dot{B}/\dot{F}}{(\bar{R}+1)\cdot\dot{B}/\dot{F}-1}\cdot(\bar{x}_{\mathrm{a}}-x_{\mathrm{Fa}})+x_{\mathrm{Fa}}$$
$$x_{\mathrm{b}}=\frac{(\bar{R}+1)\cdot\dot{B}/\dot{F}}{(\bar{R}+1)\cdot\dot{B}/\dot{F}-1}\cdot(\bar{x}_{\mathrm{b}}-x_{\mathrm{Fb}})+x_{\mathrm{Fb}}$$
$$x_{\mathrm{c}}=1-x_{\mathrm{a}}-x_{\mathrm{b}} \tag{4.68}$$

Equation (4.68) represents a straight line (mixing line) through $\dot{F}$ on the triangular diagram. The states of the liquid below ($\dot{\bar{L}}$) and above ($\dot{L}$) the feed point must lie on the mixing line, as indicated in Figure 32. The position of the operating line changes above the feed point because the quantity of liquid is altered. The following holds:

$$x_{\mathrm{a}}=\frac{\bar{R}\cdot y_{\mathrm{a}}^{*}+x_{\mathrm{Ba}}-x_{\mathrm{Fa}}\cdot\dot{F}/\dot{B}}{\bar{R}+1-\dot{F}/\dot{B}}$$
$$x_{\mathrm{b}}=\frac{\bar{R}\cdot y_{\mathrm{b}}^{*}+x_{\mathrm{Bb}}-x_{\mathrm{Fb}}\cdot\dot{F}/\dot{B}}{\bar{R}+1-\dot{F}/\dot{B}} \tag{4.69}$$
$$x_{\mathrm{c}}=1-x_{\mathrm{a}}-x_{\mathrm{b}}$$

The calculation is continued by alternating Equations (4.66) and (4.69) and working upward step-by-step to the top of the column. According to Equation (4.52), when starting with bottom state $\dot{B}$, the overhead stream $\dot{D}$, determined by stepwise calculation, must fall on a straight line through $\dot{F}$ and $\dot{B}$ (balance line around the column).

The concentrations of components a, b, and c calculated in this way are plotted as a function of the number of equilibrium stages n, as shown in Figure 33. The medium-boiling substance b can pass through a concentration maximum in the column. Furthermore, a concentration jump occurs at the feed point within the column.

4.3.4. Problems Arising in Column Calculations

Calculation of a ternary rectification, discussed in Section 4.3.3, is basically very simple and can be done with a personal computer. However, a few problems often complicate the calculation.

Choice of Reflux Ratio. The values used in practice for the reflux ratio R and the reboil ratio $\bar{R}$ are ca. 10 – 30 % higher than the minimum values. The relationships for calculating $R_{\min}$ and $\bar{R}_{\min}$ in the most important cases in Section 4.3.2 apply to ideal mixtures and to weakly nonideal mixtures. However, mixtures that deviate more strongly from nonideal behavior can produce a pinch point above or below the feed point. The reflux ratio can then be determined only by iterative column calculation.

Choice of Bottom State. The bottom composition $x_{\mathrm{B}i}$ is the iteration variable in the calculation process described in Section 4.3.3. A poorly estimated value of $x_{\mathrm{B}i}$ often gives unreasonable concentrations in the first run, e.g., concentrations >1 or <0. A useful approach is limitation of the possible bottom state as described in Section 4.3.1.

Even if the choice of bottom composition is satisfactory, unreasonable concentrations can still be obtained in the rectifying section of the column. This can be avoided by starting with estimated values of the distillate composition $x_{\mathrm{D}i}$ for calculation of the rectifying section. The calculation begins at the top and bottom of the column, and continues step-by-step until the feed point is reached. Estimated values are checked with the mixing calculation at the feed point. For real mixtures, this procedure is effective; however, iterations are required at each step of the calculation in the rectifying section because equilibrium relationships cannot be solved for liquid concentrations.

Improvement of Estimated Values. The material balance around the column is generally not fulfilled after the first calculation. A new bottom composition must be chosen which complies better with the balance around the column. No physically based criterion is available to improve the estimated values, which is the most severe handicap associated with column calculations. Indeed, serious convergence problems often occur at this point, especially in the case of highly nonideal systems.

Choice of Feed Point. For binary mixtures, feed is introduced at that point along the column at which the liquid concentration in the column is identical with the composition of the feed. This is not possible in ternary rectification because the compositions in the column usually differ from that of the feed. As a rule, the concentration of only one substance can be made equal to that of the feed. Other substances undergo irreversibe changes of state during mixing which energetically impair separation. A series of criteria are described in [32] for optimal choice of feed point; most aim at decreasing the irreversibilities.

Consideration of Enthalpy Balance. The calculation process described in Section 4.3.3 is based on the assumption of constant vapor and liquid loads in each section of the column. If these criteria (presented in Section 4.2.2) are not adequately fulfilled, the enthalpy balance must be considered in addition to the material balance. This complicates the calculation.

4.4. Rectification of Multicomponent Mixtures

The methods and equations used in ternary rectification and described in Section 4.3 can be applied directly to multicomponent mixtures. Changes in liquid concentration in the column at very high reflux ratio, $R \to \infty$, are represented by distillation curves. For ideal mixtures,

$$x_{\mathrm{D}i} = \frac{\alpha_{ik}^{n} \cdot x_{\mathrm{B}i}}{1 + \sum_{j=1}^{k-1} \left(\alpha_{jk}^{n} - 1\right) \cdot x_{\mathrm{B}j}} \tag{4.70}$$

The material balance around the column gives

$$\dot{F} \cdot x_{\mathrm{F}i} = \dot{D} \cdot x_{\mathrm{D}i} + \dot{B} \cdot x_{\mathrm{B}i} \tag{4.71}$$

These two sets of equations do not fully describe the separation. Further data are necessary, such as the relative amount of overhead product $\dot{D}/\dot{F}$ and the concentration of a component at one end of the column, i.e., the value $x_{\mathrm{D}i}$ or $x_{\mathrm{B}i}$. One extreme value for composition of the distillate is the requirement $x_{\mathrm{D}a} = 1$ with $x_{\mathrm{D}i \neq a} = 0$; the other extreme is the requirement $x_{\mathrm{B}k} = 1$ with $x_{\mathrm{B}i \neq k} = 0$, i.e., a component is separated as a pure overhead or bottom product. The area within which fractionation products $\dot{D}$ and $\dot{B}$ can be located is limited by these two extremes. However, unlike three-component mixtures (Figs. 24, 25, 26), clear representation of the separation area of multicomponent mixtures is not possible.

Relationships pertaining to operation at minimum reflux ratio $R_{\min}$ can also be applied directly to multicomponent mixtures. The requirement that the overhead product should not contain the highest boiling component k leads to, e.g.,

$$R_{\min} = \frac{1}{\sum_{j=1}^{k-1} \left(\alpha_{jk} - 1\right) \cdot x_{\mathrm{F}j}^{*}} \tag{4.72}$$

A single separation is selected from the entire separation region (see Fig. 27). The distillate composition obtained for this separation is

$$x_{\mathrm{D}i} = \frac{\left(\alpha_{ik} - 1\right) \cdot x_{\mathrm{F}i}^{*}}{\sum_{j=1}^{k-1} \left(\alpha_{jk} - 1\right) \cdot x_{\mathrm{F}j}^{*}} \tag{4.73}$$

After the relative amount of overhead product $\dot{D}/\dot{F}$ has been established, the composition of the bottom product $\dot{B}$ can be determined from the material balance around the column. Even the relationships determined for separation of the low boiler and the high boiler can be applied directly to multicomponent mixtures.

Figure 34. Rectification of a five-component mixture showing changes in liquid concentration as a function of the number of equilibrium stages
a) Butane; b) Pentane; c) Hexane; d) Heptane; e) Octane

In principle, the step-by-step calculation described in Section 4.3.3 for a ternary mixture can also be applied to multicomponent systems. The result of a calculation for a five-component system is illustrated in Figure 34. However, the more components present in the mixture, the more serious is the convergence problem. The chosen starting values of concentration at one end of the column must be close to the correct solution. Specification of the concentration of the more volatile components in the bottom product or of the less volatile components in the overhead product is especially difficult; estimated values may differ from the correct solution by several orders of magnitude. Hence, step-by-step calculation, which uses the concentration at one end of the column as the iteration variable, is unsuitable.

Several more effective methods for column calculation are available [33–37]. These produce accurate results without the use of simplifying assumptions, such as ideal mixtures or constant $\dot{L}/\dot{G}$ ratios [33]. They are based on MESH equations (i.e., *M*aterial balance, *E*quilibrium relationship, *S*ummation of all substances, and enthalpy balance *H*). The MESH equations are formulated for each equilibrium step in such a way that a tridiagonal matrix is obtained. The nonlinear set of equations is solved iteratively. The iteration variable is not the composition of the overhead or the bottom product, but usually the temperature profile or the loads in the column. The theta convergence method [34] and the Newton – Raphson method [35] have been employed successfully to improve estimated values.

Figure 35. Schematic of batch rectification

These calculation methods are highly developed. They have been applied to systems with two liquid phases [36] and to systems with superimposed chemical reactions [37] in the liquid.

Exact multicomponent column calculation, without simplifying assumptions, is mathematically very complex. Programs of this type are

commercially available and it is not generally advisable to develop them oneself.

5. Batch Rectification

Batch rectification of liquid mixtures is of great industrial importance; it is used extensively in the laboratory and in small production units. The main advantage of batch rectification over continuous operation is that a single apparatus can process many different liquid mixtures. The mixture at hand and different product requirements can be taken into account by simply changing the reflux ratio. This technique can also be extended to a multicomponent mixture; components are separated by collecting the overhead products in separate receivers.

Figure 35 represents a setup for batch rectification. The boiler is filled with the liquid mixture (L) and heated. Vapor flows up the column and is condensed at the top. Initially, the entire condensate is usually returned to the column as reflux (i.e., $R \rightarrow \infty$). This countercurrent considerably improves separation (cf. Section 4.1). After some time, a portion of the overhead condensate is withdrawn continuously as distillate. The liquid in the boiler is increasingly depleted of the more volatile components, whereas the vapor at the top becomes enriched in these substances. The volume of liquid in the boiler simultaneously decreases, resulting in a highly increased concentration of less volatile substances in the boiler.

5.1. Batch Rectification of Binary Mixtures

The calculation of batch rectification in binary mixtures is based on the Rayleigh equation, derived in Section 3.2.1 for batch distillation. Application of this equation to the rectification of L moles of liquid requires the use of x_{D}, the mole fraction of the more volatile component in the mass stream, leaving the balance (i.e., the distillate) instead of $y*$ in Equation (3.14):

$$\frac{\mathrm{d}L}{L} = \frac{\mathrm{d}x}{x_{\mathrm{D}} - x} \tag{5.1}$$

The concentration of distillate x_{D} depends on the phase equilibrium, the separation efficiency of the column (number of equilibrium steps n or number of transfer units N_{OG}), and the reflux ratio R:

$$x_{\mathrm{D}} = f\,(x, \alpha, n, R)$$

For binary mixtures, the course of the function f is usually determined graphically on the $y-x$ diagram. Calculations depend on the operating mode.

5.1.1. Operation at Constant Reflux Ratio

For operation at constant reflux ratio, the separation efficiency of the column (e.g., number of equilibrium steps n), the reflux ratio R, and the starting concentration x_0 are specified. The amount of product D, the mean composition x_{Dm} of the product, and the energy requirement for rectification are determined.

Integration of Equation (5.1) gives

$$\ln \frac{L}{L_0} = \int_{x_0}^{x} \frac{\mathrm{d}x}{x_{\mathrm{D}} - x} \tag{5.2}$$

where L_0 is the initial amount of liquid in moles. Integration of the right-hand side of this equation requires determination of the correlation $x_{\mathrm{D}} = f\,(x, \alpha, n, R)$. In a binary system, this is usually done graphically on the $y-x$ diagram, as shown in Figure 36. A composition x_{D1} is assumed, and an operating line is drawn, followed by the usual determination of the concentration x_1 in the boiler, e.g., by stepping off. Subsequently, another distillate concentration x_{D2} is assumed, and the corresponding x_2 is determined in an analogous manner and so on. The operating lines are all parallel because R is assumed to be constant. In this way, the correlation between distillate concentration x_{D} and boiler concentration x can be determined point by point. The integral in Equation (5.2) is solved by using an auxiliary diagram in which the term $1/(x_{\mathrm{D}} - x)$ is plotted on the ordinate and x on the abscissa. The area A under the curve, determined point by point, from x_0 to x represents the solution to the integral. The following equation is obtained:

$$L = L_0 \cdot e^{A} \tag{5.3}$$

When $D = L_0 - L$,

$$D = L_0 \cdot \left(1 - e^A\right) \tag{5.4}$$

The mean distillate concentration x_{Dm} is calculated from the mass balance:

$$x_{\mathrm{Dm}} = \frac{L_0 \cdot x_0 - L \cdot x}{L_0 \cdot (1 - e^A)} \tag{5.5}$$

The energy (heat) requirement for the separation, Q_{R}, is calculated from

$$Q_{\mathrm{R}} = L_0 \cdot \left(1 - e^A\right) \cdot (R+1) \cdot r \tag{5.6}$$

where r is the latent heat of vaporization.

Figure 36. Correlation between the concentration x of liquid in the boiler and the concentration x_{D} of distillate at constant reflux ratio R (batch rectification of binary system a – b)

Operation at constant reflux ratio R is relatively simple. However, the distillate concentration x_{D} decreases with time, as illustrated in Figure 36. Thus, the desired product composition is achieved by having a higher starting purity than required. The reflux ratio is often increased one or more times during separation; this prevents a steep drop in product purity.

5.1.2. Operation at Constant Distillate Composition

Deterioration of the distillate concentration x_{D} over time can be avoided by continuously increasing the reflux ratio R throughout the run. The correlation between boiler concentration x and corresponding reflux ratio R is, in turn, determined graphically on the $y - x$ diagram. A reflux ratio R, and thus the position of the operating line, are specified, and the corresponding boiler concentration x is determined by stepping off. This is illustrated in Figure 37 for two different cases. The correlation obtained depends on the separation efficiency of the column and is similar to that shown in Figure 38.

Figure 37. Correlation between reflux ratio R and concentration x of liquid in the boiler at constant distillate composition x_{D} (batch rectification of binary system a – b)
Two different cases are shown and indicated by subscripts 1 and 2.

Operation at constant distillate concentration x_{D} permits direct integration of the Rayleigh equation (Eq. 5.1) to give

$$L = L_0 \cdot \frac{x_{\mathrm{D}} - x_0}{x_{\mathrm{D}} - x} \tag{5.7}$$

The quantity of distillate is calculated from

$$D = L_0 \cdot \frac{x_0 - x}{x_{\mathrm{D}} - x} \tag{5.8}$$

The energy requirement depends on the reflux ratio R, which is variable. Hence, only a differential equation can be given:

$$dQ_R = dD \cdot (R+1) \cdot r \tag{5.9}$$

By using the correlation $dD = -dL$, the following relationship can finally be obtained from Equations (5.7) and (5.9):

$$dQ_R = L_0 \cdot r \cdot (x_D - x_0) \cdot \frac{R+1}{(x_D - x)^2} \cdot dx \tag{5.10}$$

Integration gives

$$Q_R = L_0 \cdot r \cdot (x_D - x_0) \cdot \int_{x_0}^{x} \frac{R+1}{(x_D - x)^2} \cdot dx \tag{5.11}$$

The term on the right-hand side of Equation (5.11) is integrated graphically by using an auxiliary diagram. The boiler concentration x is plotted on the abscissa vs. $(R+1)/(x_D - x)^2$ on the ordinate. The area A under the curve between x_0 and x gives the value of the integral. Hence, the heat requirement is

$$Q_R = L_0 \cdot r \cdot (x_D - x_0) \cdot A \tag{5.12}$$

In practice, operation at constant distillate concentration x_D is laborious because the reflux ratio R changes (Fig. 38) and must constantly be readjusted. On the other hand, this occurs automatically during the rectification of mixtures such as 1-butanol – water which show an immiscibility region and form a heterogeneous azeotrope (Fig. 39). In this case, part of the separation efficiency is furnished by the decanter.

5.1.3. Operation with Minimum Energy Requirement

The two operating modes described in Sections 5.1.1 and 5.1.2 require different quantities of heat Q to obtain the same amount and composition of product. Generally, less energy is required for the operation at constant distillate concentration. However, in the energetically optimal operational mode, the distillate concentration usually decreases slowly and the reflux ratio increases steadily. Pontryagin's maximum principle can be used to calculate the correlation between reflux ratio R and boiler concentration x [38]. Energy savings of up to ca. 20 % can be achieved, which justify this more laborious method only in special cases.

Figure 38. Correlation between boiler concentration x and reflux ratio R at constant distillate concentration x_D as a function of the number of equilibrium steps n

5.2. Batch Rectification of Multicomponent Mixtures

Multicomponent batch rectification is also represented by the Rayleigh equation. For each component i in the mixture,

$$\frac{dL}{L} = \frac{dx_i}{x_{Di} - x_i} \tag{5.13}$$

This set of equations can only be solved numerically.

Figure 40 shows the result of a calculation with a constant reflux ratio R for a quaternary system. The changes in distillate concentration x_{Di} clearly indicate that as rectification progresses, the individual components of the starting mixture are successively obtained as distillate in highly pure states. The pure substances can be collected in order of decreasing volatility by changing the receiver at the appropriate time. The boiler is gradually depleted of the low-boiling component (a) early in rectification; concentrations of the higher boiling substances b, c, and d increase simultaneously. After most of

Figure 39. Batch rectification of a mixture of 1-butanol – water with heterogeneous azeotrope formation
A) Flow diagram; B) McCabe – Thiele diagram for two different reflux ratios R_1 and R_2 (the shaded area denotes the immiscibility region)

substance a has been separated, the boiler is depleted of substance b, followed by substance c. Finally, the highest boiling substance d is obtained in pure form in both the boiler and the distillate.

Batchwise distillation of the same mixture is shown in Figure 12. Comparison of Figures 12 and 40 shows clearly that rectification produces a sharper separation than distillation. Rectification can be improved considerably by using a larger number of equilibrium stages in combination with a higher reflux ratio.

When the internal loads are much larger than the distillate load (i.e., $R \to \infty$), the equation derived for batch distillation (Eq. 3.24) can be applied to batch rectification. The relative volatility α_{ik} is replaced by the term α_{ik}^{n}, where n is the number of equilibrium stages. Using the mole fraction constraint $\Sigma x_i = 1$ gives

$$\sum_{i=1}^{k} \left[x_{i0} \cdot (L/L_0)^{\alpha_{ik}^{n}-1} \; (x_k/x_{k0})^{\alpha_{ik}^{n}} \right] = 1 \qquad (5.14)$$

This relationship can be used to determine the enrichment of individual substances as a function of the number of equilibrium stages n at a very high reflux ratio $R \to \infty$.

The operational mode described in Section 5.1.3 with minimum energy requirements can, in principle, also be extended to multicomponent mixtures. The calculation is described in

[39]; in addition, a chemical reaction in the liquid is taken into account.

Figure 40. Concentration profile for batch rectification of a quaternary mixture of butane (a), pentane (b), hexane (c), and heptane (d)
Reflux ratio R = 2.33; number of equilibrium stages $n = 5$; —— mole fraction x_i in boiler; – – – mole fraction x_{Di} in distillate.

The calculation procedures described hitherto contain a number of simplifications. For instance, a straight operating line was assumed in each case, but this is valid only when the vapor and liquid loads in the column are constant (see Section 4.2.2). Furthermore, liquid holdup in the transfer elements in the column has not been considered. The real, constantly present liquid holdup in the column can greatly influence the purity of the individual substances at the top of the column [40].

6. Industrial Rectification Processes

Rectification is a very important separation process used widely in industry. Years of commercial use and adaptation to important separations have resulted in the development of more complex and efficient processes.

6.1. Binary Rectification

A very sophisticated binary rectification process has been developed for the recovery of oxygen and nitrogen from air, which is basically the separation of an almost ideal two-component mixture. The separation is conducted in two steps (Fig. 41 A). Pure nitrogen is recovered as overhead product from column C-1 and fed as reflux to a second separating column C-2. Actual separation into the products nitrogen and oxygen takes place in the second column C-2.

If the feed is introduced as a gas – liquid mixture and pure gaseous nitrogen is withdrawn from C-2, then only one condenser is required for column C-1 and one reboiler for column C-2.

If column C-2 is operated at a lower pressure than column C-1, the bottom temperature of C-2 is lower than the overhead temperature of C-1; i.e., the waste heat from column C-1 can be used to heat column C-2. In the Linde double column, C-2 is placed on top of C-1 in such a way that the condenser and reboiler are combined (Fig. 41 B) [41]. The column is operated without external heat input. Energy is supplied by the fall in pressure from 0.55 to 0.13 MPa, provided the feed contains as much vapor as is released in the form of gaseous product.

6.2. Multicomponent Separation

Complete separation of a multicomponent mixture into individual components requires several rectification steps.

As discussed in Chapter 4, a ternary mixture can be separated to only a limited extent into an overhead product stream $\dot{D}$ and a bottom product $\dot{B}$. Figure 24 shows the possible position of the two fractions on a triangular diagram. In special cases, pure overhead product a or pure bottom product c can be separated. The remaining binary fraction must subsequently be separated into the pure substances in a second column.

Figures 42 A and 42 B show the two separation paths a and c, respectively. In an alternative approach (Fig. 42 C, path a – c), the first column produces an overhead product without the high boiler c and a bottom product without the low boiler a. Two additional columns are then required to separate these binary fractions. The medium boiler b appears, in one case, as the bottom product and, in the second case, as the overhead product. As discussed in Chapter 7, this alternative is energetically the most favorable at high concentrations of medium boiler b.

Figure 41. Recovery of oxygen and nitrogen from air by rectification
A) With two separate columns C-1 and C-2; B) With Linde double column

The separation of ternary mixtures often involves side columns. A side column does not represent another separating path, merely a different equipment design for path a or c. The lower section of the second column is combined with the first column, as depicted in Figure 43 for path a, thereby eliminating a heat exchanger. This type of design offers no energetic advantages. On the contrary, heat $\dot{Q}_{\mathrm{R1}}$ must be supplied at a higher temperature, which is an exergetic disadvantage. In addition, internal loads in the shaded part of the column are increased. This design is advantageous only when the amount of the medium-boiling substance b is relatively low.

For the complete separation of a four-component mixture, 21 different separation paths are possible. However, as discussed in Chapter 7, the energetically optimal separating sequence is usually the following:

Analogously, 651 different separation paths are available for the separation of a five-component mixture! Here too, the energetically optimal path can easily be found by using the methods presented in Chapter 7.

In practice, the separation sequence of multicomponent mixtures is often determined by other limiting conditions, e.g., stability or corrosiveness of individual substances, danger of explosion, toxicity, tendency to stick to column internals, etc. In all these cases, the difficult substance should, if possible, be separated first. Thus, the energy requirement is only one of many aspects determining the choice of separating sequence.

Figure 42. Paths for complete separation of a ternary mixture

6.3. Separation of Heterogeneous Azeotropic Mixtures

Azeotropic points constitute a barrier to separation by rectification. A heterogeneous azeotrope can be overcome by use of a decanter. For example, in Figure 44, separation of the binary nitromethane – water mixture requires two columns, C-1 and C-2, but both pure substances are removed as bottom products (Fig. 44 A). The vapor composition at the top of each column is approximately that of the azeotrope (Fig. 44 B). Hence, both vapor streams can be combined and condensed in the same condenser. The resulting two-phase mixture goes through a decanter S-1. The nitromethane-rich phase x_{F2} is fed into column C-2, and the aqueous phase is returned to column C-1. Because water is the bottom product in one of the columns (C-1), steam used for heating can be fed directly into the column and no reboiler is required.

In ternary mixtures, several distillation fields can occur which are separated from each other by distillation boundaries (see Sections 4.3 and 6.4). As in binary azeotropes, these distillation boundaries cannot be crossed during rectification. However, if phase splitting occurs, the distillation boundary can be crossed by separation in a decanter.

Separation of an acetone – water – butanol mixture illustrates this procedure (Fig. 45) [42]. The water – butanol mixture forms a heterogeneous azeotrope; the distillation boundary runs from the azeotrope to the low boiler acetone (Fig. 45 B). Separation is carried out in two columns (Fig. 45 A). Acetone is withdrawn overhead from the first column C-1. The bottom fraction $\dot{B}1$ lies in the shaded two-phase range and is separated into a water-rich phase $\dot{S}1$ and a butanol-rich phase $\dot{S}2$ in a decanter S-1. Because $\dot{S}2$ is located in a different distillation area from $\dot{S}1$, butanol can be withdrawn from column C-2 as bottom product. The composition of the overhead fraction from C-2 is approximately that of the heterogeneous azeotrope and can also be fed into the decanter.

Figure 43. Use of a side column in the separation of a ternary mixture
Shaded portion of the second column in the conventional two-column design (A) can be combined with the first column (B). The remainder of the second column is called the side column and may be either a rectifying or a stripping section. In this figure, it is a rectifying section.

6.4. Separation of Binary Azeotropic Mixtures by Changing System Pressure

Many mixtures contain a minimum-boiling azeotrope which allows the position of the azeotrope to be shifted substantially by changing system pressure. An important example is the mixture tetrahydrofuran – water (Fig. 46) [43]. As shown in Figure 46 B, this mixture forms a binary minimum azeotrope, which shifts toward the low-boiling substance (tetrahydrofuran) at lower system pressure.

The binary azeotrope can be crossed by first separating the high-boiling substance (water) at low pressure (0.1 MPa) in column C-1 (Fig. 46 A). The composition of the overhead product $\dot{D}1$ should be as close as possible to that of the azeotrope at this pressure. After the pressure has been increased to 0.8 MPa, $\dot{D}1$ is fed into a second column C-2. At the higher pressure in this column, the azeotrope forms at a lower concentration of low boiler (tetrahydrofuran), which can then be removed as bottom product. The overhead product of column C-2 ($\dot{D}2$), preferably in the vapor state, is returned to column C-1 after pressure reduction. Hence, column C-1 has a liquid feed $\dot{F}$ and a vapor feed $\dot{D}2$; its operating line shows two bends (Fig. 46 B).

The overhead temperature of column C-2 is higher than the boiling temperature of column C-1 [43]. Therefore, the requirements for an indirect (thermal) column coupling are fulfilled (see Section 7.3).

Figure 44. Flow diagram (A) and phase diagram (B) for separation of the binary mixture water – nitromethane
The water – nitromethane mixture forms an immiscibility region (shaded area) with one heterogeneous azeotrope. Complete separation is possible by using two columns C-1 and C-2 and a decanter S-1. The vertically hatched region on the y – x diagram represents the area between the operating line and the equilibrium curve in which the number of equilibrium steps n or transfer units N_{OG} is determined.

6.5. Separation of Azeotropic Mixtures with an Entrainer (Azeotropic and Extractive Distillation)

Binary azeotropic mixtures can be separated into pure substances by the addition of an auxiliary substance called an entrainer. The choice of entrainer must permit easy separation of the resulting ternary mixture (a, b, and entrainer e) into the starting components a and b as overhead or bottom product. Ternary mixtures possessing this property have at least one distillation boundary; i.e., the ternary mixture has several distillation fields (see Section 4.3).

6.5.1. Process Description

Figure 47 A shows a general flow diagram and Figure 47 B the corresponding triangular diagram for the separation of a binary maximum-boiling azeotrope with an entrainer. Substance b is separated overhead in column C-1 and lies in the same distillation field as the feed $\dot{F}$. The separation boundary is crossed by admixing the entrainer e with the bottom fraction $\dot{B}1$ of column C-1. Because the mixing point $\dot{M}2$ lies in the other distillation area of the triangular diagram, the second substance (a) can be separated as an overhead product in column C-2. The bottom fraction of column C-2 ($\dot{B}2$) is fed into column C-3, where the entrainer is recovered and returned to column C-2 in fraction $\dot{B}3$. The overhead fraction of column C-3 ($\dot{D}3$) still contains a considerable amount of substance b, which is separated by returning this fraction to the feed. Thus, the distillation boundary is recrossed and the mixture is again in the distillation field where substance b can be separated. This system can also be used for minimum azeotropes, but pure

Figure 45. Flow diagram (A) and phase diagram (B) for separation of the ternary mixture acetone – water – 1-butanol (p = 101.3 kPa)
The existence of an immiscibility region (shaded area) permits complete separation of the mixture in two columns C-1 and C-2 with an intermediate separator S-1.

substances a and b are then taken from the bottom of the columns.

This generalized separation process contains three separating columns and two recycling steps. Six fractions are obtained from the three separating columns. Three of the fractions are products a and b and the entrainer e; two lie on the separation boundary. The remaining fraction of column C-2 lies in the same separation field as the entrainer. The two recycling steps allow the separation boundary between the distillation fields to be crossed twice. This is possible only when the entrainer and the feed are located in different separation areas, which is always achieved by using an entrainer-rich fraction instead of a pure entrainer in the process. Such processes are generally known as *azeotropic distillation.*

6.5.2. Choice of Entrainer

The entrainer must permit the recovery of products a and b at the top or bottom of the rectification columns. This is possible only if the distillation curves on the triangular diagram either start or end at a and b (see Section 4.3). Figure 48 shows the minimum qualitative requirements that must be met by the entrainer.

In the case of a maximum-boiling binary azeotrope (Fig. 48 A – C), components a and b in the starting mixture are low-boiling substances; i.e., the distillation curves terminate at points a and b. The entrainer used must ensure that the distillation curves of both binary mixtures a – e and b – e terminate at a and b, respectively. This condition is fulfilled when entrainer e constitutes the high boiler of the system (Fig. 48 A). When the entrainer is a medium-boiling substance, component a can be separated, but component b can be recovered only if the mixture b – e forms a maximum azeotrope (Fig. 48 B). With a low-boiling entrainer (Fig. 48 C), mixtures b – e and a – e must both form a maximum azeotrope. Products a and b leave the rectification column overhead.

If a minimum-boiling binary azeotrope occurs (Fig. 48 D – F), a and b are high-boiling substances; i.e., the distillation curves start at a and b. This must also be the case in a ternary system. This condition is always fulfilled when the entrainer is a low-boiling substance (Fig. 48 F). If the entrainer has a boiling temperature between that of a and b, pure b can be separated;

Figure 46. Flow diagram (A) and phase diagram (B) for separation of a binary tetrahydrofuran – water mixture in two columns, C-1 and C-2, operating at different pressures
This mixture contains a minimum azeotrope, whose position can be shifted by changing system pressure. Hatched region represents area between the equilibrium curves and the operating lines in which the number of equilibrium steps n or transfer units N_{OG} is determined.

however, substance a can be recovered only if the mixture a – e forms a minimum azeotrope (Fig. 48 E). If the entrainer is a high-boiling substance (Fig. 48 D), a and b can be separated only if the entrainer forms a minimum azeotrope with both substances. Substances a and b are obtained as bottom products.

Thus, a binary mixture with a maximum azeotrope can generally be separated into its two components only if the entrainer is higher boiling than the pure substances or if it forms high-boiling azeotropes (i.e., maximum azeotropes). On the other hand, a mixture with a minimum azeotrope requires a low-boiling entrainer or the formation of low-boiling azeotropes. In other words, only azeotropes of the same type occur in one process.

6.5.3. Entrainment Rectification of Azeotropic Mixtures in Combination with Other Separation Methods

The generalized rectification scheme shown in Figure 47 A requires three steps in separate rectification columns. However, inclusion of other operations is sometimes advantageous, e.g., decantation, desorption, absorption, or extraction.

Decantation. Decantation can be used in place of a rectification column if the entrainer forms a heterogeneous azeotrope; this represents a simplification of the general rectification scheme. Because heterogeneous azeotropes are always minimum azeotropes and only azeotropes of the same type can occur in one process, decanters can be used only with mixtures that exhibit a minimum azeotrope.

Figure 47. Flow diagram for the separation of binary mixture a – b with a maximum azeotrope by using an entrainer e
A) Flow diagram: components a and b are obtained as pure overhead products from columns C-2 and C-1, respectively. In mixtures with a minimum azeotrope, pure substances a and b are taken from the bottom of the columns. B) Triangular phase diagram: the ternary mixture is divided into two distillation fields by a distillation boundary running from the entrainer to the maximum azeotrope. Rectification separation is possible only within one distillation field. The distillation boundary is crossed by the admixing of entrainer e.
—— Distillation boundary; —— Balance around the rectification column; – · – · – Mixing of two liquids

An important example is the production of absolute ethanol by using toluene as entrainer (Fig. 49) [44]. Ethanol and water form a minimum azeotrope at about 90 mol% of ethanol. According to Section 6.5.2, a low-boiling entrainer is required. However, the entrainer toluene is the highest boiling substance in the three-component mixture. Toluene forms a minimum azeotrope with ethanol and a minimum heterogeneous azeotrope with water. Hence, the entrainer complies with the separation requirements described in Section 6.5.2. In addition, a ternary azeotrope exists which has the lowest boiling temperature in the system.

Water is first separated as a bottom product in column C-1. The overhead fraction $\dot{D}1$ lies on the separation boundary, which is crossed by the admixing of a toluene-rich phase. In column C-2, ethanol is removed as bottom product. The temperature of the overhead product $\dot{D}2$ is reduced to approximately 25 °C, which brings it into the two-phase region. The toluene-rich phase $\dot{S}2$, used as entrainer, is recovered as the light phase in a decanter S-1. The water-rich phase $\dot{S}1$ is taken as the heavy phase from the decanter and combined with the feed. Separator S-1 replaces separating column C-3 in the generalized scheme shown in Figure 47.

A decanter is also used in separating pyridine – water mixtures which form a minimum azeotrope [45]. According to Figure 48, a mixture with a minimum azeotrope requires a low-boiling entrainer. In this example, however, toluene is employed, which has a boiling point between that of pyridine and water. Toluene forms a minimum azeotrope with water, so the requirements of Figure 48 E are satisfied. In addition, toluene forms a minimum azeotrope with pyridine, but this is of no importance.

The separation is shown schematically in Figure 50. Feed $\dot{F}$ is mixed with the entrainer and introduced into column C-1. Pure pyridine ($\dot{B}1$) is taken as bottom product from this column. The overhead fraction $\dot{D}1$ has the approximate composition of the heterogeneous water – toluene azeotrope. This fraction is cooled to 25 °C and separated into two liquid phases in the decanter S-1. The heavy phase $\dot{S}2$ contains mainly water, which is removed as product. The toluene-rich phase $\dot{S}1$ is returned to the process as entrainer.

In contrast to the generalized scheme shown in Figure 47 A, only one rectification column and one separator are required to separate an

Figure 48. Minimum requirements to be met by entrainer e for separation of binary mixture a – b with a maximum azeotrope (A – C) or a minimum azeotrope (D – F)
Separation into pure a and b is possible only when the distillation curves either start or terminate at a and b. If a maximum azeotrope is present, either the entrainer must be a high-boiling substance (A), or it must form new maximum azeotropes (B, C). If a minimum azeotrope is present, the entrainer must be a low-boiling substance (F) or it must form new minimum azeotropes (D, E).
Azeotropic points are represented by the large open circles.

azeotropic mixture. The favorable position of the immiscibility region permits simultaneous performance of two separating tasks, namely, separation of water as a product and recovery of the entrainer.

Desorption is used in the recovery of nitric acid from an aqueous mixture (→ Nitric Acid, treated in the A series) [46]. The system nitric acid – water forms a maximum azeotrope at a nitric acid concentration of 39 mol%. Accordingly, a high-boiling entrainer should be selected. Although sulfuric acid forms a maximum azeotrope with water at 96.8 mol% and is used as entrainer, this has no importance in the separation procedure.

The process is illustrated in Figure 51. The separation boundary is crossed by mixing approximately 46 mol% of sulfuric acid with the feed. The separation of nitric acid as overhead product $\dot{D}1$ is possible in the separation field in which the mixing point $\dot{M}$ is located. After air and steam stripping, the bottom product $\dot{B}1$ is practically free of nitric acid, giving fraction $\dot{\bar{B}}1$. The entrainer-rich fraction $\dot{B}2$ is recovered from $\dot{\bar{B}}1$ by removing water as fraction $\dot{D}2$ in a vacuum distillation column C-2.

A) Flow diagram showing one rectification column C-1 and one distillation column C-2
B) Triangular phase diagram
—— Distillation boundary; —— Rectification; – · – · Mixing of liquids

The unusual feature of this process is the desorption step in the lower part of column C-1, which permits crossing of the separation boundary between the two distillation fields, as shown in Figure 51 B. Consequently, the separation of water and the simultaneous recovery of entrainer are possible. Thus only one recycling step and two separation columns are required; column C-2 is used for simple distillation. Furthermore, the entrainer and the feed are located in the same distillation field, which should not be permitted according to the general process scheme. However, the separation boundary is curved to such an extent that the mixing of $\dot{B}2$ and $\dot{F}$, both of which lie in the same distillation field, results in crossing of the separation boundary. However, the composition of the feed must then be almost the same as that of the binary azeotrope.

A similar process is used to concentrate dilute hydrochloric acid [47] with sulfuric acid as entrainer.

Absorption can be conveniently used to separate mixtures containing a minimum azeotrope, such as ethanol – water. The high boiler is separated in the first column C-1 (see Fig. 52 A). The overhead fraction has approximately the same composition as the binary azeotrope. The vapor mixture is fed into an absorber A-1, in which the entrainer is used to wash out primarily the higher boiling component b. Pure substance a is thus obtained at the top of the absorber. The loaded washing agent from the absorber is introduced into column C-2 where entrainer e is recovered as bottom product. The overhead product of C-2 contains substances a and b, and is returned to column C-1.

The entrainer does not have to satisfy the criteria in Figure 48 because the azeotrope distillation boundary is crossed in the absorption column. However, the entrainer must have a greater affinity for the high boiler b than for the low boiler. In the dehydration of ethanol, a hygroscopic liquid (e.g., ethylene glycol) is used for this purpose.

The equipment required can be simplified, as shown in Figure 52 B, by placing the absorption column A-1 on top of the rectification column C-1, thereby eliminating a reflux condenser. The heavy entrainer also flows through the rectification column C-1. The high boiler b is withdrawn from the top of column C-2. A relatively large number of separations are carried out in this way. Important examples are the separation of ethanol – water with diethylene glycol, of benzene – cyclohexane with ani-

line, and of butadiene – butene with N-methyl-2-pyrrolidone [48], [49].

The process shown in Figure 52 B is generally known as *extractive distillation,* although it actually involves absorption and not extraction. A more correct name would be absorptive distillation.

7. Energy Economization in Rectification

The energy requirement $\hat{W}$ for separation of a mixture into its pure components i can be calculated [50] from

$$\hat{W} = -\hat{R}\cdot T\cdot \sum x_{\mathrm{F}i}\cdot \ln\left(\gamma_i \cdot x_{\mathrm{F}i}\right) \tag{7.1}$$

This relationship is independent of the separation method and merely describes the reversal of the mixing procedure (see Eq. 2.30).

Energy required for rectification is supplied in the form of heat. The exergy E describes the ability of heat to be converted into work:

$$E = Q\cdot\left(T_1 - T_0\right)/T_1 \tag{7.2}$$

where Q is the amount of heat, T_1 the heat input temperature, and T_0 the ambient temperature. The work performed W is calculated from the exergy difference between the heat input temperature T_1 and the heat output temperature T_2:

$$W = Q\cdot T_0\left[\frac{1}{T_2} - \frac{1}{T_1}\right] \tag{7.3}$$

Thus, energy consumption depends not only on the quantity of heat Q, but also on the temperature.

In a rectification column, a quantity of heat $\dot{Q}_{\mathrm{R}}$ is required at the bottom of the column at temperature T_{R} and a quantity of heat $\dot{Q}_{\mathrm{C}}$ is removed at the top at temperature T_{C}. The following relationship holds:

$$\dot{Q}_{\mathrm{R}} + \dot{Q}_{\mathrm{C}} \approx 0, \text{ where} T_{\mathrm{R}} - T_{\mathrm{C}} > 0 \tag{7.4}$$

The temperature difference $T_R - T_C$ is usually ca. 5 – 20 °C, so exergy losses are normally small. However, the heat required for rectification is usually supplied in the form of steam at temperature $T_1 \gg T_R$ and is removed by cooling water at $T_2 \ll T_C$. In this way, larger amounts of exergy are lost during separation than are actually necessary.

Means of saving energy during rectification include reducing the heat requirement $\dot{Q}$ and minimizing the temperature difference $(T_1 - T_2)$ between heat input and output (see also → Energy Management in Chemical Industry, Chap. 6.

7.1. Single Columns

7.1.1. Reduction of Heat Requirement

The heat requirement $\dot{Q}$ of a single rectification column can be minimized best by effective heat exchange between the warm products and the cold feed, and also by efficient insulation of the column. Furthermore, the operational reflux ratio R should be kept as small as possible; optimum ratios are in the range of $R = 1.05 - 1.1\, R_{min}$ [51].

The thermal state of the feed (caloric factor φ) greatly influences the heat requirement of a column. The theoretical minimum values $\dot{Q}/(\dot{F} \cdot r)$ for ideal binary mixtures are given in Figure 53.

The heat requirement of a liquid feed (Fig. 53 A) is greater by the additive term x_{Fa} than that of a vapor feed (Fig. 53 B). In a vapor feed, the latent heat is used only in the top of the column. Indeed, the vapor feed should be condensed in the reboiler before it is introduced into the column (Fig. 53 C). In this way, latent heat is used in both parts of the column, which leads to a lower external heat-input requirement $\dot{Q}_R$. The column can then be operated without an external heat source if the feed concentration y_{Fa} is low and the relative volatility α is high. This mode of operation is often employed in low-temperature processes, but the feed pressure must be higher than the operating pressure in the column. Hence, a vapor feed is preferable to a liquid feed. However, a liquid should not be prevaporized because then the total energy requirement is higher than with a liquid feed (Fig. 53 D).

When the feed is composed of several streams with different compositions, multiple feeding should be considered (see Fig. 20). Optimal choice of feed point and careful column control are very important.

7.1.2. Reduction of Exergy Losses

The use of intermediate reboilers and condensers has been proposed frequently. Although they do not lower the heat-input requirements of a column, part of the heat required can be supplied at a lower temperature and removed at a higher temperature (i.e., exergy losses are reduced). This method offers practical advantages only if variable external heat sources (e.g., steam with variable pressure) or heat sinks are available, or if thermal coupling is possible (Section 7.3.2).

Exergy losses can be effectively reduced by utilizing waste heat obtained at the top of the column to produce low-pressure steam (Fig. 54 A) [52]. No steam is "consumed" during rectification, and high-pressure steam is converted into low-pressure steam. Thus, exergy, and not energy, is consumed. If a low-pressure steam system is not available, steam can be returned to the high-pressure system after compression (Fig. 54 B).

Systematic development of this operational mode leads to incorporation of a heat pump with supplementary circulation (Fig. 54 C). The selection of a suitable working medium for the heat pump always arises. The substances separated in the rectification column can often be used to advantage as a working medium for the heat pump. Consequently, the pump can be integrated into the rectification [53]. Utilization of the overhead product as a heat pump medium (Fig. 55 A) is usually more favorable than utilization of the bottom product (Fig. 55 B).

The integrated heat pump is used in many industrial low-temperature plants (e.g., ethylene plants) [54]. In high-temperature processes, a problem occurs because the high molecular mass substances present have a very small adiabatic exponent $\kappa = c_p/c_v$. Therefore, the vapor temperature barely rises on compression; it may fall below the dew point and cause machine damage due to condensation [55].

7.2. Optimal Separation Sequences for Multicomponent Mixtures

As described in Section 6.2, a large number of different separating sequences exist for complete fractionation of multicomponent mixtures. Investment and operating costs depend on the separating path selected. Operating costs are determined primarily by energy costs. Heat requirements for the different separating paths in a ternary mixture are presented below.

The minimal heat-input requirements for separation of an ideal ternary mixture a – b – c into pure substances by the a, c, and a – c paths can be formulated in general terms as described in Chapter 4 and are illustrated in Figure 56.

In path a (Fig. 56 A) the low-boiling substance a is removed first. The remaining binary mixture b – c is fed into column C-2 and separated into b and c. If the feed is a boiling liquid, then according to Section 4.2.5 the following expression holds for the minimum heat requirement of column C-1:

$$\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r} = \left(R_{\mathrm{a,min}} + 1\right)\cdot x_{\mathrm{Fa}} \tag{7.5}$$

where r is the molar latent heat of vaporization of the feed and $R_{\mathrm{a,\,min}}$ is defined in Equation (4.64).

The minimum heat requirement of column C-2 is given by

$$\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r} = x_{\mathrm{Fb}} + \frac{1 - x_{\mathrm{Fa}}}{\alpha_{\mathrm{bc}} - 1} \tag{7.6}$$

The heat requirement for the entire process is

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r} = \frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r} + \frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r} \tag{7.7}$$

Values of $\dot{Q}_{\min}/(\dot{F}\cdot r)$ for the mixture 2,2-dimethylbutane – 2-methylpentane – hexane are in the range of 3.4 to 6.3. In Figure 56 A, they are plotted in parametric form against the feed composition of the mixture on a triangular diagram; they increase more rapidly as the concentration of medium-boiling substance b increases.

In path c, the high boiler c is removed from column C-1 (Fig. 56 B). The overhead product

Figure 54. Reduction of exergy losses during rectification

Figure 55. Schematic of integrated heat pumps using the overhead product (A) or the bottom product (B) as the pump medium

Figure 56. Minimum heat requirement $\dot{Q}/(\dot{F}\cdot r)$ as a function of the feed composition for separation of a ternary mixture of 2,2-dimethylbutane (a), 2-methylpentane (b), and hexane (c)
A) Path a; B) Path c; C) Path a – c
Relative volatility: $\alpha_{ac} = 1.887$; $\alpha_{bc} = 1.329$. Shaded area in C represents the concentration range in which path a – c is more favorable than paths a and c.

of column C-1 (ab) is fed in the vapor state into column C-2, where pure products a and b are separated. For a boiling-liquid feed, the heat required by column C-1 is

$$\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}=\bar{R}_{\mathrm{c},\min}\cdot x_{\mathrm{Fc}} \tag{7.8}$$

where $\bar{R}_{\mathrm{c},\,\min}$ is obtained from Equation (4.65). For a liquid feed, the heat required by column C-2 is

$$\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}=x_{\mathrm{Fa}}+\frac{1-x_{\mathrm{Fc}}}{\alpha_{\mathrm{ab}}-1} \tag{7.9}$$

For the more favorable vapor feed, the heat required by column C-2 is

$$\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}=\frac{1-x_{\mathrm{Fc}}}{\alpha_{\mathrm{ab}}-1} \tag{7.10}$$

The heat requirement of the entire process is expressed by

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r}=\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}+\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r} \tag{7.11}$$

The values of $\dot{Q}_{\min}/(\dot{F}\cdot r)$ for the mixture 2,2-dimethylbutane – 2-methylpentane – hexane are in the range of 3.0 to 6.3; here again, the highest values are obtained at high concentrations of the medium boiler b (Fig. 56 B).

As discussed in Section 4.3.1, in the large number of possible rectification products from a three-component mixture, separation of the low boiler a or the high boiler c represents a special case.

In path a – c, three separating columns are required (Fig. 56 C). To obtain pure substances, the overhead product from column C-1 must be free of the high boiler c. Correspondingly, the bottom product of column C-1 must be free of the low boiler a. The overhead product should preferably be fed in the vapor state into column C-2.

In the following discussion, the assumption is made that the "preferred" separation is carried out in column C-1 (cf. Section 4.3.2.1). Thus, the reflux ratio and the heat requirement of this column reach an absolute minimum. If the feed is a boiling liquid, Equations (4.44), (4.56), and (4.57) give the following relationship for column C-1:

$$\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}=\frac{1+(\alpha_{\mathrm{ac}}-1)\cdot x_{\mathrm{Fa}}+(\alpha_{\mathrm{bc}}-1)\cdot x_{\mathrm{Fb}}}{\alpha_{\mathrm{ac}}-1} \tag{7.12}$$

The heat requirement of column C-2 for a liquid feed is

$$\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}=x_{\mathrm{Fa}}+\frac{(\alpha_{\mathrm{ac}}-1)\cdot x_{\mathrm{Fa}}+(\alpha_{\mathrm{bc}}-1)\cdot x_{\mathrm{Fb}}}{(\alpha_{\mathrm{ac}}-1)\cdot(\alpha_{\mathrm{ab}}-1)} \tag{7.13}$$

For a vapor feed, the following equation is obtained for column C-2:

$$\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}=\frac{(\alpha_{\mathrm{ac}}-1)\cdot x_{\mathrm{Fa}}+(\alpha_{\mathrm{bc}}-1)\cdot x_{\mathrm{Fb}}}{(\alpha_{\mathrm{ac}}-1)\cdot(\alpha_{\mathrm{ab}}-1)} \tag{7.14}$$

The heat requirement of column C-3 is

$$\frac{\dot{Q}_{3,\min}}{\dot{F}\cdot r}=x_{\mathrm{Fb}}+\frac{\alpha_{\mathrm{ac}}-\alpha_{\mathrm{bc}}}{\alpha_{\mathrm{ac}}-1}+ \\ +\frac{\alpha_{\mathrm{ac}}-[1+(\alpha_{\mathrm{ac}}-1)\cdot x_{\mathrm{Fa}}+(\alpha_{\mathrm{bc}}-1)\cdot x_{\mathrm{Fb}}]}{(\alpha_{\mathrm{ac}}-1)(\alpha_{\mathrm{bc}}-1)} \tag{7.15}$$

For the entire process,

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r}=\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}+\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}+\frac{\dot{Q}_{3,\min}}{\dot{F}\cdot r} \tag{7.16}$$

In Figure 56 C, the minimal heat requirement for the system 2,2-dimethylbutane – 2-methylpentane – hexane is plotted against the composition of the starting mixture and gives a series of parallel lines. Values for $\dot{Q}_{\min}/(\dot{F}\cdot r)$ are in the range of 4.2 to 5.0; they increase only slightly with increasing concentration of the medium-boiling substance b.

Comparison of heat requirements for the separating paths of a ternary mixture shows large variations depending on the composition of the feed material. If the feed contains a high concentration of the low boiler a, path a (Fig. 56 A) is the most favorable. However, if the feed contains an excess of the high boiler c, path c is preferred, as shown in Figure 56 B. Path a – c is favored when the feed contains an excess of medium-boiling substance b. The concentration range in which path a – c is most useful is indicated by the shaded area in Figure 56 C.

Path a – c requires three separating columns; i.e., it requires more equipment than the other two paths. However, this sequence is exergetically advantageous because heat is added or removed at many different temperature levels; therefore its energy-saving potential is considerable. If exploited properly, path a – c gives a more efficient separation than the other two sequences (see Section 7.3.2).

7.3. Column Coupling

Column coupling may be advantageous in processes involving several rectification columns. In *direct coupling,* columns are coupled by means of their product streams [56]. *Indirect* (*thermal*) *coupling* exploits the waste heat from one column to heat a second column. Indirect coupling is a very effective way of substantially reducing the heat requirement in rectification processes and is used more often than direct coupling. However, it increases equipment requirements; additional pumps and compressors are usually required. Direct coupling saves not only energy but also lowers equipment requirements.

7.3.1. Direct Coupling of Columns

Direct coupling of columns C-2 and C-3 is possible in separating the ternary mixture shown in Figure 56 C. Vapors of substance b are condensed at the top of column C-3 to obtain the required reflux. However, substance b must also be vaporized at the bottom of column C-2 to maintain the countercurrent in this column. Columns C-2 and C-3 can be combined by omitting a condenser and a reboiler to give column $\overline{\text{C-2}}$ (Fig. 57). The amount of heat converted in the two columns generally differs. This heat difference can be compensated with an intermediate heat exchanger. However, the equipment requirement is lower if the heat supplied at the bottom of column $\overline{\text{C-2}}$ corresponds to the maximum heat requirement of one of the two original columns C-2 or C-3, whichever is larger. Thus, the heat requirement of the entire process in Figure 57 is

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r}=\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}+\text{Max}\left[\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}\text{or}\frac{\dot{Q}_{3,\min}}{\dot{F}\cdot r}\right] \quad (7.17)$$

The individual amounts of heat are calculated by using Equations (7.12), (7.14), and (7.15). Direct coupling reduces the heat requirements, at best, to approximately two-thirds of the original amount.

In Figure 57, Equation (7.17) is applied to the mixture 2,2-dimethylbutane – 2-methylpentane – hexane. The heat requirement is presented in parametric form in terms of the feed composition. The values for $\dot{Q}_{\min}/(\dot{F}\cdot r)$ are in the range of 3.1 to 4.4, i.e., substantially lower than the values obtained without direct coupling in Figure 56 C. The lowest heat requirements are obtained in the intermediate concentration range in which $\dot{Q}_{2,\min}$ and $\dot{Q}_{3,\min}$ are almost equal; hence, omission of the smaller value results in the largest energy saving.

As a result of the direct coupling of columns C-2 and C-3, only two columns are required for path a – c. Thus, equipment requirements for all three paths are roughly the same. With regard to the heat requirement, however, path a – c is more efficient over a wider concentration range than the other two paths. The shaded part of Figure 57 represents the optimal region. Comparison with Figure 56 C shows clearly that direct coupling is particularly useful for increasing the optimal area of this path.

Another variation in the direct coupling of columns for path a – c is shown in Figure 58 A. However, the heat requirement is not lowered because the steam for column C-1 must also be produced in column $\overline{\text{C-2}}$. Nevertheless, omission of two heat exchangers reduces the equipment requirement.

The column construction shown in Figure 58 B is still more efficient. Here, columns C-1 and $\overline{\text{C-2}}$ are combined to give a single column in which the middle part is divided by a vertical wall [57]. This construction can be applied easily to packed columns and involves lower investment costs. However, its disadvantage is that all the heat is added at the highest temperature and removed at the lowest. In addition, the different separations on the right and left sides of the partition must be carried out at the same packing depth. Thus, the amounts of liquid in both parts of the column must be controlled carefully.

Direct coupling of columns can also be employed in the separation of quaternary mixtures. Of the 21 different possible separation sequences, Figure 59 shows the path in which the overhead product and the bottom product from each column are free of the high boiler and the low boiler, respectively. If each column is operated at the lowest possible reflux ratio, the preferred separation according to Section 4.3.2.1 is obtained. The amounts and compositions of all material streams are clearly fixed. If a liquid feed is introduced into column C-2, the composition of the bottom product of C-2 is identical with the overhead product of C-3 (for a vapor

Figure 57. Heat requirement $\dot{Q}/(\dot{F}\cdot r)$ as a function of the feed composition for the path a – c with direct column coupling in the separation of a ternary mixture of 2,2-dimethylbutane (a), 2-methylpentane (b), and hexane (c)
The shaded portion represents the concentration range in which this path is energetically more favorable than paths a and c (cf. Fig. 56).

Figure 58. Reduction of the equipment requirement for separation of a ternary mixture by direct column coupling
A) Omission of the heat exchanger in the first column; B) Combination of two columns to give a single column in which the middle part is divided by a vertical wall

Figure 59. Path a – d in the separation of a quaternary mixture
A) Without direct coupling; B) With direct coupling

feed the products are in equilibrium). Thus, the product streams can be combined and fed into column C-5. Six columns are required for complete separation into pure substances.

Direct coupling can again be carried out between columns C-2 and C-3, C-4 and C-5, and C-5 and C-6 (Fig. 59 B). Hence, only three columns are required for the process. The heat requirement is

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r}=\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}+\mathrm{Max}\left[\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}\,\mathrm{or}\,\frac{\dot{Q}_{3,\min}}{\dot{F}\cdot r}\right]+$$
$$+\mathrm{Max}\left[\frac{\dot{Q}_{4,\min}}{\dot{F}\cdot r},\frac{\dot{Q}_{5,\min}}{\dot{F}\cdot r}\,\mathrm{or}\,\frac{\dot{Q}_{6,\min}}{\dot{F}\cdot r}\right] \qquad (7.18)$$

Direct coupling reduces the heat requirement of a four-component mixture by as much as one-half of the original value.

Another example of the direct coupling of two columns is the separation of an acetone – water – 1-butanol mixture by using the separator shown in Figure 45. The vapor at the bottom of column C-1 has approximately the same concentration as the vapor at the top of column C-2. Hence, the two columns can be combined [58], as shown in Figure 60. A condenser and a reboiler can be omitted, and the heat requirement of the new column $\overline{\text{C-1}}$ corresonds to the value for either column C-1 or column C-2, whichever is larger.

The examples show that direct coupling is particularly useful and always leads to substantial reduction of the heat requirement. It also simplifies equipment because considerably fewer columns and heat exchangers are required. This, in turn, lowers investment costs.

7.3.2. Indirect Coupling of Columns

In indirect (thermal) coupling, waste heat from one column is used to heat another column. Generally, the columns must be operated at different pressures to obtain the necessary temperature gradient. Because the vapor pressure of liquids increases exponentially with temperature, relatively large changes in pressure are needed to produce a significant temperature change.

Hence, indirect coupling is of particular interest when the feed contains close-boiling species.

Figure 60. Direct column coupling in the separation of acetone – water – 1-butanol
For schematic without direct coupling, see Figure 45 A.

7.3.2.1. Binary Mixtures

If a process contains several columns, indirect coupling should always be considered. Sometimes separation in two thermally coupled columns is preferable to a single column. Figure 61 A shows two columns operating in parallel: each completely separates the binary starting mixture. However, the pressure p_2 of column C-2 is much lower than the pressure p_1 of column C-1. Hence, the overhead temperature of column C-1 is higher that the bottom temperature of column C-2, so waste heat from column C-1 can be utilized to heat column C-2. Thus, the heat requirements of rectification can be halved. The feed, however, must be compressed to the higher pressure p_2.

A variation of this process permits indirect coupling of the two columns at a lower pressure difference (Fig. 61 B). Pure substance b is taken from the bottom of column C-1, and an a-rich fraction containing a significant amount of b is taken from the top of the column. The vapor is used to heat column C-2. The condensate thus obtained is partially returned to column C-1 as reflux and partially fed into column C-2, where it is completely separated into pure substances a and b.

In Figure 61 C, column C-1 functions as a prefractionator from which an a-rich overhead fraction and a b-rich bottom fraction are fed to column C-2. Separation takes place in C-2. The heat requirement of column C-2 is lowered by this double feeding. Indirect coupling of the columns permits prefractionation without additional heat requirement.

Modifications of the process in Figure 61 are employed in industry. For instance, the air-separation process described in Figure 41 is comparable to the process shown in Figure 61 C. Exceptional features of air separation also permit omission of the reboiler in column C-1 and the condenser in column C-2.

Requirements for the indirect coupling of columns are always fulfilled in the separation of azeotropic mixtures by pressure changes. Figure 62 shows indirect coupling in the process used to separate a mixture of water and tetrahydrofuran. Separation of this mixture in two separate columns without indirect coupling is discussed with Figure 46; the temperature at the top of column C-2 is 136 °C, but the temperature at the bottom of column C-1 is only 100 °C. Therefore, indirect coupling is possible, and the heat requirement is reduced to ca. 65 % of the original value [59]. Equipment requirements are also substantially lower.

7.3.2.2. Ternary Mixtures

Separation of ternary mixtures requires at least two rectification columns; therefore, indirect column coupling is possible.

Indirect coupling of the two columns of path a is shown in Figure 63 A. Column C-2 operates at a higher pressure, so its waste heat can be used to heat column C-1. Indirect coupling reduces the heat requirement of the entire process to a value equivalent to the larger value of the two original columns. Thus,

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r} = \mathrm{Max}\left[\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}\,\mathrm{or}\,\frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}\right] \tag{7.19}$$

Figure 61. Indirect (thermal) column coupling in the separation of binary mixtures
A) Two columns operated in parallel with complete separation in each column; B) Separation of the a-rich overhead product from C-1 in C-2; C) Prefractionation to give enriched products in C-1 followed by complete separation in C-2. Colum C-1 operates at a lower pressure (p_1) than column C-2 (p_2).

The quantities $\dot{Q}_{1,\min}$ and $\dot{Q}_{2,\min}$ can be calculated by using Equations (7.5) and (7.6). Indirect coupling reduces the heat requirement of the process by as much as a half.

Figure 63 A shows the values calculated for $\dot{Q}_{\min}/(\dot{F} \cdot r)$ from Equation (7.19) for the mixture 2,2-dimethylbutane – 2-methylpentane – hexane. The heat requirement is plotted in parametric form against the feed stream $\dot{F}$ and is in the range of 1.7 – 4.0, i.e., considerably lower than the values obtained without indirect coupling (Fig. 56 A). In the intermediate concentration range, the heat required by each of the two columns is about the same; therefore, omission of one quantity of heat results in the largest energy saving. Here, indirect coupling halves the heat requirement.

Analogously, the indirectly coupled columns used in path c are shown in Figure 63 B. The liquid overhead product of column C-1, which operates at a higher pressure, is introduced into column C-2. The heat requirement of the entire process is

Figure 62. Indirect (thermal) column coupling to separate an azeotropic mixture of water and tetrahydrofuran by changing system pressure
For schematic without indirect coupling, see Figure 46 A.

Figure 63. Minimum heat requirement $\dot{Q}/(\dot{F}\cdot r)$ as a function of feed composition for separation paths with indirect coupling in the separation of a ternary mixture of 2,2-dimethylbutane (a), 2-methylpentane (b), and hexane (c)
A) Path a; B) Path c; C) Path a – b (direct and indirect coupling)
Relative volatility: $\alpha_{ac} = 1.887$; $\alpha_{bc} = 1.329$.

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r} = \text{Max}\left[\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r} \text{ or } \frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r}\right] \tag{7.20}$$

The individual quantities of heat are calculated from Equations (7.8) and (7.9).

The results of Equation (7.20) are shown on the triangular diagram in Figure 63 B. The parametric representation clearly shows the transition between the two quantities of heat. Energy savings are at a maximum in the transition range. However, a 50 % reduction is not achieved because the feeding of vapor into column C-2 represents a coupling (see Fig. 56 B), which is, however, less effective than that shown in Figure 63 B.

The indirect coupling of path a – c is presented in Figure 63 C. Here, too, overhead product from the high-pressure column C-1 is fed into column C-2 in the liquid state. The minimum heat requirement of the process is

$$\frac{\dot{Q}_{\min}}{\dot{F}\cdot r} = \text{Max}\left[\frac{\dot{Q}_{1,\min}}{\dot{F}\cdot r}, \frac{\dot{Q}_{2,\min}}{\dot{F}\cdot r} \text{ or } \frac{\dot{Q}_{3,\min}}{\dot{F}\cdot r}\right] \tag{7.21}$$

The individual quantities of heat are calculated from Equations (7.12), (7.13), and (7.15).

The results of Equation (7.21) for the mixture 2,2-dimethylbutane – 2-methylpentane – hexane are presented in parametric form on the triangular diagram shown in Figure 63 C. A series of parallel lines are obtained in each region. The value $\dot{Q}_{1,\min}$ is always smaller than $\dot{Q}_{2,\min}$ or $\dot{Q}_{3,\min}$ so that only two regions are obtained on the triangular diagram.

Values for $\dot{Q}_{\min}/(\dot{F}\cdot r)$ range from 1.6 to 3.3 and are lower than those obtained for paths a and c (Figs. 63 A and 63 B). Only if the mixture has a very low content of medium boiler b are the three processes shown in Figure 63 equivalent. In all other cases, path a – c with direct and indirect coupling is the most favorable sequence.

7.4. Design of Heat-Exchanger Networks

In thermal processes, different quantities of heat must generally be added and removed at many points and at different temperatures. Optimal coupling of the heat sources and heat sinks of the process allows minimization of external heat transfer to and from the process. A temperature – heat flow diagram showing the values, temperatures, and signs (+ or −) of all heat quantities is extremely useful; it indicates clearly if thermal coupling is possible [60].

Figure 64 A represents the separation of a ternary mixture by using path a – c with ten heat exchangers (E-1 – E-10). The signs and temperatures of the quantities of heat for all exchangers are presented on the temperature – heat flow diagram (Fig. 64 B). The heat exchanger E-1 can be coupled thermally only with E-8, E-9, or E-10 because only there is the temperature at which the heat is supplied higher than that at which it is removed. However, the quantities of heat converted are relatively small; thus, almost the entire amount of heat (146 MJ/kmol) must be added from an external heat source (heating steam) and removed by an external heat source (cooling water).

The same path, but with direct and indirect coupling, is shown in Figure 65. The feed is heated in heat exchanger E-10 by heat transfer from the separated products. It is subsequently brought to boiling with heating steam in exchanger E-1. External heat is added to the column via E-2 and removed via E-5 at a much lower temperature. The heat of condensation from column C-1 is transferred to column C-2 via intermediate heat exchangers E-3 and E-6. This is possible only if the temperature of E-3 is higher than that of E-6, which is guaranteed by increasing the operating pressure of column C-1 to ca. 0.25 MPa.

Comparison of Figures 64 B and 65 B shows that the total amount of heat converted is higher in the process with direct and indirect coupling. However, only about one-third of the heat must be supplied from an external source.

The design of heat-exchanger systems is of considerable importance in many processes and has been perfected [61].

8. Design and Dimensioning of Mass-Transfer Equipment

8.1. Types of Construction

The basic requirements for mass-transfer are given by

$$\dot{N} = K_{OG}\cdot A\cdot (y^* - y) \tag{8.1}$$

Figure 64. Heat flow in the separation of a mixture of 2,2-dimethylbutane (a), 2-methylpentane (b), and hexane (c) by using path a – c without direct or indirect coupling
A) Flow diagram showing columns (C-1, C-2) and heat exchangers (E-1 – E-10); B) Temperature – heat flow ($T - \dot{Q}$) diagram: the shaded areas represent the driving force, i.e., temperature difference for heat transfer.

The maximum mass-transfer rate $\dot{N}$ is obtained when all three terms of the above equation are as large as possible:

The mass-transfer coefficient K_{OG} depends on the flow condition of the liquid and vapor phases; it increases proportionally to the relative velocity. The situation is improved if new fluid elements constantly reach the phase boundary and produce a nonsteady mass transfer with short transfer times. Columns that allow constant regeneration of the contact area are particularly effective.

The contact area A for mass transfer depends on the geometry of the apparatus and the local velocities of the two phases. It is strongly affected by the column internals.

The largest driving force ($y* - y$) for mass transfer between phases is achieved when the overall flow pattern at all points in the apparatus allows countercurrent contact between equal streams of vapor and liquid without remixing. Thus, both phases must be distributed uniformly over the entire flow area.

Plate columns and *packed columns* are most often used for rectification; they guarantee excellent countercurrent flow and permit a large overall height. The internals provide a large mass-transfer contact area, which is constantly regenerated, especially in plate columns.

The use of mass-transfer machines has been proposed repeatedly for rectification. Although such devices have proved useful for extraction, they have not been accepted in rectification [62].

8.1.1. Plate Columns

Figure 66 shows the most important features of a plate column. The vapor moves up the column through perforations in the horizontal plates, and the condensed liquid flows downward as a countercurrent. However, the two phases on the individual plates exhibit cross flow relative to each other. The ascending vapor passes through

Figure 65. Heat flow in the separation of a mixture of 2,2-dimethylbutane (a), 2-methylpentane (b), and hexane (c) with direct and indirect coupling
A) Flow diagram showing columns (C-1, C-2) and heat exchangers (E-1 – E-3, E-5, E-6, E-10); B) Temperature – heat flow ($T - \dot{Q}$) diagram

the perforations into the liquid flowing across the plate, to form a large two-phase interface. The two phases subsequently separate; the vapor rises to the plate above, whereas the liquid flows over the exit weir into the downcomer, which is usually segmental in shape. Some of the liquid accumulates in each downcomer; this compensates for the pressure drop caused by the vapor as it passes through the tray. The liquid then flows through an inlet onto the plate below. The orifices in the tray floor can have various designs.

Bubble-cap plates were used almost exclusively for many years. Their construction prevents liquid from leaking downward (weeping) through the plate. However, complex bubble caps are relatively expensive and have a higher pressure drop than other designs.

Sieve plates have become increasingly important. They are inexpensive, have a high separation efficiency, and produce a low pressure drop across the plate. Previously, sieve plates were used with holes of ca. 1-mm diameter, which were easily blocked by dirt particles. However, hole diameters of 12 and sometimes 25 mm are now employed.

Valve plates are a relatively new, but widely used, development. The cross section of the orifices in the plate is adjusted to prevent the liquid from leaking through the plate at low vapor loads and to avoid excessive pressure increase at high vapor loads.

Many other variations of the sieve, valve, and bubble-cap plates are also available, e.g., Performkontakt [63].

8.1.2. Packed Columns

Figure 67 shows the most important features of a packed column. Vapor enters at the bottom of the column and flows upward through the

free cross-sectional area of the internals. Liquid flows downward countercurrently to the ascending vapor. Thus, a packed column provides countercurrent contacting of the two phases, which is crucial for good mass transfer.

Figure 66. Cutaway section of a plate column
a) Downcomer; b) Tray support; c) Sieve trays; d) Manway; e) Outlet weir; f) Inlet weir; g) Side wall of downcomer; h) Liquid seal

Figure 67. Cutaway section of a packed column with a structured wire gauze packing (Sulzer) [64]
a) Liquid distributor; b) Liquid collector; c) Structured packing; d) Support grid; e) Manway; f) Liquid redistributor

The liquid should wet the column packing (random or structured) as completely as possible to maximize the mass-transfer contact area between phases. The type of packing greatly influences the efficiency of the column. *Random dumped packings* made of specially formed particles (rings, saddles, cf. Fig. 80) are often used: their surface area should be as large as possi-

ble; they should have a low flow resistance; and they should be distributed homogeneously in the column (no large cavities). *Structured packings* comply more readily with these requirements and are used widely.

Figure 68. Schematic of a plate column showing important parameters
A) Vertical section
a) Bubble-cap plate; b) Valve plate; c) Sieve plate
d_{cap} = cap diameter; d_v = valve diameter; d_h = hole diameter; h_{cl} = height of skirt clearance of downcomer; h_w = weir height; H = plate (tray) spacing; $\dot{V}_L$ = volumetric flow rate of liquid
B) Cross section
d) Small holes with narrow spacing; e) Large holes with wide spacing
A_d = cross-sectional area of downcomer; A_{ac} = active cross-sectional area; D_c = column diameter; l_{cl} = skirt clearance length of downcomer; l_L = length of liquid path; l_w = weir length

Uniform distribution of liquid over the entire cross-sectional area is very important. In Figure 67, a cascade distributor is used for this purpose. Although the initial liquid distribution is uniform, liquid maldistribution usually occurs as the height of the packing increases; this can greatly impair separation efficiency. Therefore, the height of individual packed beds is limited to 3 – 6 m. Liquid leaving the first packing bed is collected and led into an annular channel, where it is thoroughly mixed. It is then redistributed by a second cascade distributor. Smaller columns generally use side deflectors to redistribute the liquid.

The internals of the column must offer minimum resistance to vapor flow. Modern packings have a relative free cross-sectional area of more than 90 %. The liquid collector and distributor should also reach this value. The support grating for the packing is often a barrier to flow, especially when its free cross-sectional area is blocked by the lowest particle layer.

8.1.3. Criteria for Use of Plate or Packed Columns

Proper choice of equipment is very important for effective and economical separation. An unambiguous choice is not always possible because both plate and packed columns can be modified to fulfill different requirements.

Plate columns are generally employed when large-diameter (> 1 m) towers are required; several downcomers are often necessary. The vapor load in plate columns must be kept within a relatively narrow range; only valve plates allow greater operational flexibility. The liquid load, however, can be varied over a very wide range.

Plate columns can also be operated efficiently at very low liquid loads, e.g., in vacuum operation. However, the relatively high pressure drop involved is a disadvantage, especially when the separation requires a large number of plates. Plate columns have a relatively large liquid holdup in both the two-phase layer on the plate and the downcomer. This compensates for fluctuations in feed composition. However, the high holdup results in a high liquid residence time in the column, which may lead to the decomposition of thermally unstable substances. The

holdup is also significant when a chemical reaction occurs during rectification. Special cap designs allow the liquid on the tray to be retained for short shutdown periods so that column operation can be resumed quickly. A further advantage of plate columns is that heat-exchanger coils incorporated above the plate allow heat to be added or removed easily. Plate columns are also relatively insensitive to impurities in the liquid.

Packed columns are used almost exclusively when small-diameter (e.g., < 0.7 m) towers are required. However, the development of structured packings permits the use of packed columns with very large diameters.

Packed columns are extremely flexible as far as vapor load is concerned, but they require a minimum liquid load, which often excludes their use in vacuum operation. Newly developed structured packings, however, have brought substantial progress to this area too.

The small pressure loss in packed columns, in comparison with plate columns, is a tremendous advantage. The danger of decomposition of thermally unstable substances is also less in packed columns because liquid holdup is very small.

Figure 69. Typical bubble-caps and valves
a) Glitsch valves; b) Bayer bubble-cap; c) Linde bubble-cap; d) ACV bubble-cap; e) Montz KSG bubble-cap; f) Stahl valve; g) Koch valves

Packed columns are not suitable for the treatment of liquids that contain particulate contaminants or tend to crystallize. They are, however, less sensitive to foaming mixtures than plate columns. Ceramic random packings are resistant to corrosion.

8.2. Dimensioning of Plate Columns

Schematic cross sections of bubble-cap, valve, and sieve plates together with their most important dimensions are shown in Figure 68. Typical examples of bubble caps and valves are shown in Figure 69. Standard geometrical dimensions, developed on the basis of practical experience, are given in Table 1.

8.2.1. Operating Region of Plate Columns

Careful column dimensioning requires determination of the entire operating region and the design parameters so that a safety margin can be maintained with respect to the limits for liquid and vapor loads.

The operating region is represented in Figure 70, where the vapor load $\dot{V}_G$ is plotted against the liquid load $\dot{V}_L$ [65]; loads are expressed relative to the active plate area A_{ac}. Several factors limit the flow rate. The upper limits are absolute and cannot be exceeded. However, the lower limits are not absolute; although the column can be operated below these limits, separation efficiency deteriorates.

Figure 70. Operating region of a plate column
Operating boundaries due to: a) Entrainment; b) Froth height; c) Downcomer capacity; d) Weeping; e) Minimum crest over weir
A_{ac} = active plate area; $\dot{V}_G$ = volumetric flow rate of vapor; $\dot{V}_L$ = volumetric flow rate of liquid

Maximum Vapor Load. The vapor load in a plate column can be increased to the point where the vapor blows the liquid off the plate in droplets. The liquid then no longer moves countercurrently to the vapor, and column operation stops.

Table 1. Standard values for the construction of plate columns

Figure 71. Correlation of the capacity factor for sieve plates according to FAIR [69]
Plate spacing H: a) 0.91 m; b) 0.61 m; c) 0.46 m; d) 0.30 m; e) 0.23 m; f) 0.15 m
Values for C'_G are shown for weir height $h_w \leq 0.15$ H, hole diameter $d_h \leq 6.35$ mm, and liquid surface tension = 0.02 N/m. The capacity factor is calculated from the chart value C'_G with the formula: $C_G = C'_G \left(\frac{\sigma}{0.02}\right)^{0.2}$
Corrections must be made for the relative free hole area φ as follows: $\varphi \geq 0.101$, $C_G = C'_G$
$\varphi = 0.08$, $C_G = 0.9 \cdot C'_G$
$\varphi = 0.06$, $C_G = 0.8 \cdot C'_G$

The maximum possible vapor load is calculated by using the Souders and Brown [66] equation:

$$w_G = C_G \sqrt{(\varrho_L - \varrho_G)/\varrho_G} \tag{8.2}$$

where w_G is the superficial vapor velocity, C_G is the capacity factor, ϱ_L is the density of the liquid, and ϱ_G is the density of the vapor. If the F factor, defined by $F = w_G \cdot \sqrt{\varrho_G}$, is used as a measure of vapor load, the above equation becomes

$$F = C_G \sqrt{\varrho_L - \varrho_G} \tag{8.3}$$

The capacity factor C_G must be determined experimentally. Several correlations are described in [67], [68]. The most frequently used correlation is that of FAIR, who found that C_G is proportional to $\sigma^{0.2}$; it is presented in Figure 71 [69].

A theoretical relationship assumes that the vapor on the plate forms the continuous phase while the liquid is dispersed into individual droplets [70]. The diameter d of the drop is expressed in terms of the critical Weber number We_{cr}, which is computed by using the vapor velocity through the orifices (holes, slots) in the plate.

$$d = We_{cr} \cdot \sigma / F_h^2 = We_{cr} \cdot \sigma \cdot \varphi^2 / F^2 \tag{8.4}$$

where σ is the surface tension of the liquid, φ is the relative free hole area, F is the vapor loading factor defined in Equation (8.3), and $F_h = F/\varphi$.

A balance of forces between the resistance to flow and the weight minus the buoyancy is obtained for the diameter of the drops that are suspended in the vapor stream above the plate:

$$d = \frac{3}{4} \frac{\zeta_{sp}}{(\varrho_L - \varrho_G) \cdot g} \cdot F^2 \tag{8.5}$$

where ζ_{sp} is the frictional coefficient of a sphere and g is the acceleration due to gravity. Eliminating the drop diameter from both equations yields

$$F_{max} = \left(\frac{4 \cdot We_{cr}}{3 \cdot \zeta_{sp}}\right)^{0.25} \cdot \left[\varphi^2 \cdot \sigma \cdot (\varrho_L - \varrho_G) \cdot g\right]^{0.25} \tag{8.6}$$

According to [71], the critical Weber number is approximately 12. If the frictional factor ζ_{sp} is assumed to be 0.4 (the value obtained for a sphere in a turbulent region), then

$$F_{max} = 2.5\left[\varphi^2 \cdot \sigma\left(\varrho_L - \varrho_G\right) \cdot g\right]^{0.25} \tag{8.7}$$

This purely theoretical equation corresponds not only to the measured values, but also to Fair's correlation [69]. A proportionality to $\sigma^{0.25}$ is found in this equation, whereas FAIR empirically obtained $\sigma^{0.2}$. The dependence on the relative free hole area φ also corresponds to the $\varphi^{1/2}$ relationship in Equation (8.7).

Equation (8.7) describes the process of blowing off the plate and is applicable only to plate towers with very large plate spacings. When plate spacings are smaller, the height of the two-phase layer, and not the blowing-off process, is the limiting factor that determines maximum vapor load. This height must always be less than the plate spacing for safe operation.

Minimum Vapor Load. The vapor load on the column plate can be decreased to the point where the plate is not uniformly exposed to the vapor or the liquid leaks through the plate. Both conditions are undesirable because they lower plate efficiency. According to MERSMANN [72], a sieve plate is uniformly exposed to vapor when the Weber factor exceeds the critical value 2 at the holes; thus,

$$F_h \geq \sqrt{2 \cdot \sigma / d_h} \tag{8.8}$$

where d_h is the hole diameter.

If the Froude number Fr exceeds a critical value, the liquid can be prevented from leaking through a sieve plate. According to RUFF [73],

$$F_h \geq \sqrt{0.37 \cdot d_h \cdot g \cdot \left(\varrho_L - \varrho_G\right)^{1.25} / \varrho_G^{0.25}} \tag{8.9}$$

Equations (8.8) and (8.9) are evaluated for three different systems in Figure 72. At small hole diameters up to 2 mm, uniform vapor distribution is the limiting factor, and the minimum vapor load required decreases with increasing hole diameter. At hole diameters greater than 2 – 3 mm, weeping of liquid through the plate becomes the decisive factor; the minimum vapor load then increases with increasing hole diameter.

Figure 72. Minimal vapor load of sieve plates for three different systems
a) Air – water; b) Benzene – toluene; c) Isobutane – *n*-butane

Equations (8.8) and (8.9) do not take into account the influence of the liquid load on the lower vapor load limit, although large liquid loads require a somewhat higher minimum vapor load to prevent weeping of liquid through the plate. However, if weeping does occur, it does not lower separation efficiency significantly.

Maximum Liquid Load. Liquid flows down the column through the downcomers due to the influence of gravity. This driving force permits a limited liquid flow rate $\dot{V}_L$ only. The four following empirical criteria are generally used to determine the maximum liquid flow rate [74]:

1) The weir load $\dot{V}_L/l_w$ (l_w = weir length) should be less than 60 $m^3\,m^{-1}\,h^{-1}$.
2) The liquid velocity in the downcomer should not exceed ca. 0.1 m/s.
3) The liquid residence time in the downcomer should be greater than 5 s.
4) The height of the clear liquid in the downcomer should not exceed half the plate spacing H.

If the entire downcomer is filled with a vapor – liquid mixture with a relative liquid holdup $\bar{\varepsilon}_{Ld}$, the following equation is obtained [75]:

$$\frac{\dot{V}_L}{l_{cl}} = 0.61 \cdot \bar{\varepsilon}_{Ld} \cdot h_{cl} \cdot \sqrt{2 \cdot g \cdot H \cdot \left(\varrho_L - \varrho_G\right) / \varrho_L \cdot \left(1 - \frac{h_p + h_L}{\bar{\varepsilon}_{Ld} \cdot H}\right)} \tag{8.10}$$

where l_{cl} is the skirt clearance length of the downcomer, h_{cl} is the skirt clearance height, h_p is $\Delta p/\varrho_L g$, and h_L is the clear liquid height on the plate. The parameter $\bar{\varepsilon}_{Ld}$ is unknown; an approximate value of 0.4 can be employed for nonfoaming systems. Further details are given in [76].

Minimum Liquid Load. In theory, a column plate can be operated even at very small liquid loads because the height of the two-phase layer on the plate is guaranteed by the exit weir. However, at extremely low liquid loads, liquid flows unevenly across the plate, which decreases the separation efficiency (see Section 8.2.3). Accordingly, the minimum height of the weir overflow is usually set at ca. 5 mm; this corresponds to a minimum weir load of $\dot{V}_L/l_w \approx 2\,m^3\,m^{-1}\,h^{-1}$. In small-diameter columns, however, this value may be considerably lower.

Entrainment of liquid by the vapor also determines the minimum liquid load.

8.2.2. Two-Phase Flow in Plate Columns

The behavior and properties of the two-phase layer on the plates are important for the mode of action of plate columns. The two-phase layer has three basic structures:

1) *Bubble Regime.* The liquid forms the continuous phase; the vapor rises in the liquid in the form of discrete bubbles.
2) *Drop Regime.* The liquid is dispersed in the form of drops in the continuous vapor phase.
3) *Froth Regime.* This regime represents a transition from the bubble to the drop system. The vapor – liquid layer is agitated intensively, so no clearly dispersed phase is formed.

The bubble regime can exist only at very high pressures for the following reasons: At the minimum gas load, the vapor load at the holes in the plate floor should not fall below $F_h \approx 5$ (see Fig. 72); therefore, the vapor velocity at the holes is expressed by $w_{Gh} = 5/\sqrt{\varrho_G}$. However, the bubbles rise at a velocity of ca. 0.1 – 0.2 m/s. Only if the density of the vapor ϱ_G is very high (i.e., at high pressure) does the vapor velocity in the holes reach the velocity at which the bubbles rise, as is necessary in a bubble regime.

At low pressures, the vapor velocity is much higher than the velocity at which the bubbles rise. Thus, bubbles build up at the orifices, forming a region of very high vapor content, which breaks through the two-phase layer suddenly and rises upward. This jerky mode of operation is responsible for the two-phase froth regime.

The vapor load at which the transition to the drop regime (phase inversion) occurs is of special interest [75]. When the liquid level on the plate h_L is high, phase inversion occurs at $F/F_{max} \approx 0.65$. However, if h_L is very low, phase inversion can occur much earlier. Hence, column dimensioning requires a minimum vapor penetration depth of ca. 20 mm.

Plate columns are usually operated in the froth region. Operating conditions approach the drop regime only in vacuum rectification.

The *relative liquid holdup* ε_L is a very important parameter of the two-phase layer. Published values can be summarized by the following equation:

$$\varepsilon_L = 1 - (F/F_{max})^{0.28} \tag{8.11}$$

This relationship is valid only if $\varphi \cdot \varrho_L/\varrho_G > 50$. Determination of the relative liquid holdup for smaller values of this parameter is described in [75].

Expressions for the *height of the two-phase (froth) layer* h_f given in the literature are not dimensionally correct, nor do they adequately represent the limiting conditions. The following equation summarizes most of the known measured values [75]:

$$h_f = h_w + \frac{1.45}{g^{1/3}}\left(\frac{\dot{V}_L/l_w}{\varepsilon_L}\right)^{2/3} + \left(\frac{125}{g\cdot(\varrho_L - \varrho_G)}\right)\cdot \cdot\left(\frac{F - 0.2\sqrt{\varrho_G}}{1-\varepsilon_L}\right)^2 \tag{8.12}$$

where h_w is weir height, l_w weir length, and g the acceleration due to gravity. The influence of the liquid load on the height of the two-phase layer is covered primarily by the second term, which represents the overflow height of the exit weir. The last term takes into account upward spraying of liquid caused by the vapor, which occurs only in the froth and drop regimes. Therefore, it should be considered only when

$$F - 0.2\sqrt{\varrho_G} > 0.$$

Equation (8.12) applies only when vapor is allowed to pass through the liquid up to the exit weir. If the exit weir is preceded by a calming zone, vapor – liquid separation can take place, with the result that clear liquid flows over the exit weir. The height of the foaming two-phase layer is then expressed by

$$h_f = \left[h_w + \frac{1.45}{g^{1/3}} \cdot \left(\dot{V}_L / l_w \right)^{2/3} \right] / \varepsilon_L \tag{8.13}$$

Equation (8.13) usually gives a larger value for h_f than Equation (8.12).

Figure 73. Dependence of entrainment on the vapor load [75]
Curves are plotted at indicated values of the parameter $(H - h_f) \cdot \Delta\varrho \cdot g/F^2_{max}$ for a hole diameter of less than 10 mm (H = plate spacing, h_f = height of two-phase froth layer, $\Delta\varrho$ = density difference, g = acceleration due to gravity).

Liquid Entrainment. Vapor flowing through the two-phase layer always entrains droplets of liquid. Entrainment is undesirable because it disturbs the countercurrent flow of vapor and liquid. In the drop regime, relative entrainment $\dot{V}_E/\dot{V}_G$ ($\dot{V}_E$ is the volume flow rate of entrained liquid) can be expressed as a function of the relative vapor load F/F_{max} in an entrainment diagram. Published data are correlated in Figure 73 [75]. This diagram applies to all three plate designs: sieve, valve, and bubble-cap plates. Entrainment depends strongly on vapor load. A tenfold increase in vapor load increases entrainment by a factor of ca. $10^4 - 10^5$. A sudden increase in entrainment occurs at a relative vapor load F/F_{max} of ca. 0.65; this is due to the change from the froth to the drop regime.

Liquid Mixing in the Two-Phase Layer. In plate columns, liquid flows across the plate to the exit weir; i.e., the liquid exhibits cross flow relative to the vapor. Mass transfer between phases causes a concentration profile in the liquid, which greatly influences plate efficiency. The two-phase layer on the plate is agitated intensely, particularly in the froth and drop regimes. This results in partial mixing of the liquid on the plate, which in turn reduces the differences in liquid concentration. According to the dispersion model, the degree of liquid mixing on the plate can be represented by the dimensionless Péclet number *Pe:*

$$Pe = \frac{l_L^2}{D_E \cdot \tau_L} \tag{8.14}$$

where l_L is the path length of the liquid, D_E is the dispersion coefficient, and τ_L is the residence time of the liquid in the two-phase layer on the plate. The liquid is totally mixed when $Pe = 0$; the opposite case (i.e., no mixing) is called plug flow and is characterized by $Pe \to \infty$.

The dispersion coefficient D_E is obtained by modification of an equation derived by Weisshuhn [77]:

$$D_E = 1.06 \cdot h_f \cdot F \left(\frac{\varepsilon_L}{\varrho_L - \varrho_G} \right)^{1/2} \tag{8.15}$$

Equation (8.15) applies only to the froth and the drop regimes. The degree of liquid mixing in the bubble regime is usually so small that it can be neglected.

Liquid Maldistribution. To achieve optimal mass-transfer efficiency, equal amounts of vapor and liquid must be brought into contact at each site on the plate. However, uniform distribution of the liquid stream on the plate area is almost impossible to achieve in practice.

Results of tests conducted on a bubble-cap plate, 2.3 m in diameter, are presented in Figure 74 [78]. The plate was operated with a warm water – air system. As a result of the favorable mass-transfer conditions in the two-phase layer,

the air is virtually saturated with water vapor, which in turn leads to a temperature drop in the liquid. The temperatures in the froth layer on a plate are relatively easy to determine experimentally and are shown as liquid isotherms in Figure 74. These isotherms can be interpreted as lines of constant liquid residence time. In the case of plug flow (no mixing), the liquid isotherms are represented by lines parallel to the liquid inlet and outlet. The characteristic deviations of the isotherms in Figure 74 from a straight line are due to the characteristic design of the plate.

Figure 74. Liquid maldistribution on column plates represented in the form of isotherms [78]
Data were determined on a bubble-cap plate with a diameter of 2.3 m, at a vapor load F of 1.61 $\mathrm{Pa}^{1/2}$ and a relative liquid flow rate $\dot{V}_\mathrm{L}/l_\mathrm{w}$ of 10 $\mathrm{m}^3\,\mathrm{m}^{-1}\,\mathrm{h}^{-1}$.

The most important factors influencing liquid flow on the plate are the design of the inlet and outlet weirs, a highly uniform distribution of the bubble caps over the plate area, and absolutely horizontal installation of the plate [78].

Liquid – Vapor Interfacial Area. The interfacial area of the two-phase layer on the plate is very important and is conveniently expressed in a ratio to the volume of the layer. No satisfactory correlation is available for determination of the relative interfacial area a. Various procedures have yielded values that differ by a factor of 10 [75]. However, the order of magnitude of the interfacial area and its influencing factors can be estimated by using the following equation, which is valid for spherical dispersed particles [75]:

$$a = 6\,(1-\varepsilon)\,/d \tag{8.16}$$

where ε is the porosity and d is the particle diameter. Equation (8.16) can be applied to the bubble and drop regimes, but not to the froth regime. The volume fraction occupied by the dispersed phases can be computed by using Equation (8.11) for the liquid holdup ε_L. The bubble diameter d is approximately

$$d = \left[\frac{6\cdot\sigma}{(\varrho_\mathrm{L}-\varrho_\mathrm{G})\cdot \mathrm{g}}\right]^{1/2} \tag{8.17}$$

The interfacial area in the bubble regime is given by

$$a = 6\left[\frac{(\varrho_\mathrm{L}-\varrho_\mathrm{G})\cdot g}{6\cdot\sigma}\right]^{1/2}\cdot\left(F/F_\mathrm{max}\right)^{0.28} \tag{8.18}$$

Analogously, an equation for the drop regime can be obtained by using Equation (8.4) to determine the diameter of the droplet:

$$a = \frac{F^2}{2\cdot\sigma\cdot\varphi^2}\cdot\left[1-\left(F/F_\mathrm{max}\right)^{0.28}\right] \tag{8.19}$$

where φ is the relative free hole area, i.e., ratio of total hole area to active area.

Equations (8.18) (bubble regime) and (8.19) (drop regime) are evaluated for three systems in Figure 75. The froth regime cannot be calculated because a clear dispersed phase does not exist. However, the interpolated values shown in Figure 75 should approximate the real course. The interfacial area in aqueous systems is ca. 500 $\mathrm{m}^2/\mathrm{m}^3$, but in organic systems values of 1000 $\mathrm{m}^2/\mathrm{m}^3$ or more can be reached. The interfacial tension σ has a considerable effect on the area of the interface; analysis shows that

$$a \approx \sigma^{-0.57} \tag{8.20}$$

This calculation permits a rough estimation of the mass-transfer area and the most important influencing factors. The values obtained are only partially applicable to calculation of the mass-transfer efficiency of a plate column. This is because it is not known whether all parts of the interface contribute to the same extent to mass transfer between phases (cf. Section 8.2.3).

Pressure Drop of Vapor on the Plate. The pressure drop Δp of the vapor as it passes through the plate can be expressed as follows:

$$\Delta p = \Delta p_{\mathrm{d}} + \Delta p_{\mathrm{L}} + \Delta p_{\mathrm{R}} \tag{8.21}$$

The first term Δp_{d} accounts for the pressure drop through a dry plate. The second term Δp_{L} represents the pressure drop resulting from the height of liquid h_{L} on the column plate and can be formulated by

$$\Delta p_{\mathrm{L}} = h_{\mathrm{L}} \cdot \varrho_{\mathrm{L}} \cdot \mathrm{g} = h_{\mathrm{f}} \cdot \varepsilon_{\mathrm{L}} \cdot \varrho_{\mathrm{L}} \cdot \mathrm{g} \tag{8.22}$$

The last term of Equation (8.21), Δp_{R}, accounts for several residual factors including bubble formation, liquid mixing, and vertical acceleration of the liquid. This term is much smaller than the first two and can generally be neglected.

Figure 75. Calculated values for the interfacial area-to-volume ratio a of the two-phase layer on column plates
a) Isobutane – n-butane; b) Acetone – benzene; c) Air – water
- - - Bubble regime (Eq. 8.18); – · – · – Drop regime (Eq. 8.19); —— Presumed real values

Pressure Drop in Dry Sieve Plates. The pressure drop of the vapor as it passes through a dry sieve plate Δp_{d} is given by

$$\Delta p_{\mathrm{d}} = \zeta \cdot \frac{\varrho_{\mathrm{G}}}{2} \cdot w_{\mathrm{Gh}}^2 = \frac{\zeta}{2} \cdot F_{\mathrm{h}}^2 \tag{8.23}$$

A relationship for the orifice coefficient ζ can be derived from the law of conservation of energy and the law of momentum. For very thin perforated plates (i.e., when the ratio of plate thickness to hole diameter $s/d_{\mathrm{h}} \to 0$), the following formula applies:

$$\zeta = \left(\frac{1}{\alpha} - \varphi\right)^2 \tag{8.24}$$

where α is the contraction number and φ is the relative free hole area. For thick perforated plates (i.e., when $s/d_{\mathrm{h}} \gg 0$), frictional losses can be neglected and the following equation is obtained:

$$\zeta = \left(\frac{1}{\alpha} - 1\right)^2 + (1-\varphi)^2 \tag{8.25}$$

At high Reynold's numbers, a value of 0.61 is sufficiently accurate for the contraction number α.

The normal situation lies between the extreme cases described in Equations (8.24) and (8.25), and the orifice coefficient must be determined experimentally. Figure 76 shows measured values of the orifice coefficient ζ_0, i.e., for a relative free hole area $\varphi \to 0$, plotted as a function of the ratio of plate thickness to hole diameter [75]. Equation (8.24) gives a constant theoretical limit of $\zeta_0 = 2.69$ for very thin plates. A limit of $\zeta_0 = 1.41$ is obtained from Equation (8.25) for thick plates.

Figure 76. Dependence of the orifice coefficient of sieve trays (sharp-edged holes) on the ratio of plate thickness to hole diameter (s/d_{h})
Value of Reynold's number: a) 400; b) 1000; c) 5000; d) 10^4; e) 10^6
Dashed lines indicate theoretical limits.

The relationship between the orifice coefficient ζ and the relative free hole area φ differs for thin and thick plates. For thin plates, from Equation (8.24)

$$\zeta = \zeta_0 + \varphi^2 - 2 \cdot \varphi \sqrt{\zeta_0} \tag{8.26}$$

For thick plates, the following is obtained from Equation (8.25):

$$\zeta = \zeta_0 + \varphi^2 - 2 \cdot \varphi \tag{8.27}$$

In practice, the differences between Equations (8.26) and (8.27) are very small because φ does not exceed 0.2. Therefore, Equation (8.27) can be used with sufficient accuracy for most plate thicknesses.

Figure 77. Dependence of the orifice coefficient of column plates on the relative free hole area φ
Bubble-cap plates: a) Bayer; b) Montz KSG; c) Linde; d) ACV; e) Thormann 1963; f) Kirschbaum 1951

Sieve plates: m) $\zeta_0 = 1.7$; n) $\zeta_0 = 1.0$

Pressure Drop in Dry Valve and Bubble-Cap Plates. Bubble caps and valves are so complex that prediction of the pressure drop is almost impossible. Generally, the pressure drop must be measured. Both the orifice coefficient ζ of each element and the number of elements that can be accommodated per unit area depend on the prevailing construction; therefore, comparison is made with a plate orifice coefficient ζ_t:

$$\zeta_t = 2 \cdot \Delta p_d / F^2 \tag{8.28}$$

A compilation of orifice coefficients for different types of plates is shown in Figure 77 [75]. The orifice coefficient in valve plates and bubble-cap plates is always larger than in sieve plates. However, the relative free hole area φ in valve plates can be larger than in sieve plates because the danger of liquid leaking through the plate is much less. Thus, differences between the three types of plates can be minimized.

8.2.3. Mass Transfer in the Two-Phase Layer on Column Plates

In practice, mass transfer between vapor and liquid in the two-phase layer on the plate floor is usually defined by means of an efficiency factor.

In *point efficiency* E_{OG}, the concentration change along an individual stream of vapor is considered; it is defined by

$$E_{OG} = \frac{y - y_{n-1}}{y^*(x) - y_{n-1}} \tag{8.29}$$

The subscript OG means that the overall resistance has been formally placed in the gas (vapor) phase. The actual change in concentration of vapor $(y - y_{n-1})$ as it flows through the two-phase layer is related to the maximum concentration change attainable; i.e., $y*(x) - y_{n-1}$. Here, $y*$ is the vapor concentration in equilibrium with liquid concentration x at the point on the plate where the vapor stream passes through the two-phase layer.

Point efficiency is a very useful theoretical factor but has no immediate practical importance. It can reach a maximum value of 1 provided that the liquid is completely mixed throughout the head of the two-phase layer.

In practice, *plate efficiency* E_{OGM} is used and is defined by

$$E_{OGM} = \frac{y_n - y_{n-1}}{y^*(x_n) - y_{n-1}} \tag{8.30}$$

Here, the overall vapor flow through the column is considered. The actual concentration change of the total vapor $(y_n - y_{n-1})$ is related to the maximum possible change in concentration $y*(x_n) - y_{n-1}$. Here, $y*$ is the vapor concentration in equilibrium with liquid concentration x_n leaving plate n. This definition is arbitrary because the concentration usually differs at each point on the plate, and efficiencies of more than 100 % can be obtained. Although the theoretical definition of plate efficiency E_{OGM} is

unsatisfactory, it is of practical interest because it describes the separation efficiency of a real plate.

Equations (8.29) and (8.30) define the gas transfer efficiency; analogous equations are also sometimes used for the liquid transfer efficiency. However, they have no practical importance because the main resistance to mass transfer in rectification is attributed to the vapor.

The relationship between point and plate efficiency can be formulated easily when the liquid flows across the plate without mixing (plug flow). According to [79],

$$\frac{E_{\mathrm{OGM}}}{E_{\mathrm{OG}}} = \frac{\dot{L}/\dot{G}}{m} \cdot \frac{1}{E_{\mathrm{OG}}} \left[\exp\left(\frac{m}{\dot{L}/\dot{G}} \cdot E_{\mathrm{OG}} \right) - 1 \right] \tag{8.31}$$

The vapor under each plate is assumed to be completely mixed.

As a rule, the liquid in the two-phase layer on column plates is at least partially mixed. For complete mixing,

$$E_{\mathrm{OGM}}/E_{\mathrm{OG}} = 1 \tag{8.32}$$

Figure 78. Correlation between the ratio of overall plate efficiency E_{OGM} to point efficiency E_{OG} and the liquid mixing represented by the Péclet number *Pe*

The normal condition lies between the two extremes described by Equations (8.31) and (8.32). The degree of liquid mixing, which is expressed in terms of a Péclet number *Pe* (see Section 8.2.2), must then be considered. A solution [80] for this is represented graphically in Figure 78. In plug flow (no mixing), $Pe = \infty$; when $Pe = 0$, complete liquid mixing takes place. When both the Péclet number and the abscissa $E_{\mathrm{OG}} \cdot m/(\dot{L}/\dot{G})$ are large, the ratio of the plate efficiency to the point efficiency $E_{\mathrm{OGM}}/E_{\mathrm{OG}}$ becomes very large. However, for the abscissa to be very large, the liquid flow $\dot{L}$ must be small. The high residence time at low flow rates causes considerable remixing on the plate so that the parameter *Pe* in Figure 78 becomes very small. In practice, plate efficiency is also affected adversely by other processes such as liquid leakage through the plate, entrainment of liquid to the next higher plate, and maldistribution. In careful column design, the plate efficiency can be adjusted so that it is only slightly higher than the point efficiency.

Point Efficiency. The equations of mass transfer must be examined before theoretically defining the point efficiency. The following relationship is valid:

$$E_{\mathrm{OG}} = 1 - \exp\left(-N_{\mathrm{OG}}\right) \tag{8.33}$$

The overall number of gas-phase transfer units N_{OG} can be calculated from the number of transfer units in the gas N_{G} and in the liquid N_{L} by using the following equation:

$$\frac{1}{N_{\mathrm{OG}}} = \frac{1}{N_{\mathrm{G}}} + \frac{m}{\dot{L}/\dot{G}} \cdot \frac{1}{N_{\mathrm{L}}} \tag{8.34}$$

where $m/(\dot{L}/\dot{G})$ is known as the stripping factor. The number of transfer units in the vapor phase is given by

$$N_{\mathrm{G}} = \frac{\beta_{\mathrm{G}} \cdot a \cdot h_{\mathrm{f}} \cdot A_{\mathrm{ac}}}{\dot{V}_{\mathrm{G}}} \tag{8.35}$$

where β_{G} is the vapor mass-transfer coefficient, a is the relative interfacial area (Fig. 75), h_{f} is the height of the foaming layer, A_{ac} is the active transfer area, and $\dot{V}_{\mathrm{G}}$ is the volumetric vapor flow rate. Analogously, for the liquid phase,

$$N_{\mathrm{L}} = \frac{\beta_{\mathrm{L}} \cdot a \cdot h_{\mathrm{f}} \cdot A_{\mathrm{ac}}}{\dot{V}_{\mathrm{L}}} \tag{8.36}$$

Substitution of Equations (8.35) and (8.36) into Equation (8.34) gives

$$N_{\mathrm{OG}} = \frac{a \cdot \beta_{\mathrm{G}} \cdot h_{\mathrm{f}}/w_{\mathrm{G}}}{1 + m \cdot \beta_{\mathrm{G}}/\beta_{\mathrm{L}} \cdot \hat{M}_{\mathrm{L}}/\hat{M}_{\mathrm{G}} \cdot \varrho_{\mathrm{G}}/\varrho_{\mathrm{L}}} \tag{8.37}$$

where w_{G} is the superficial vapor velocity; $\hat{M}_{\mathrm{L}}$ and $\hat{M}_{\mathrm{G}}$ are the molar masses; and ϱ_{L} and ϱ_{G} the densities, of the liquid and vapor, respectively. The numerator in this equation represents mass

transfer in the vapor phase, while the denominator takes into account the additional resistance to mass transfer in the liquid.

Equation (8.37) is generally applicable and contains four unknowns that are specific to the apparatus: the relative interfacial area *a,* the height of the two-phase layer h_f, and the mass-transfer coefficients in the vapor β_G and in the liquid β_L.

Determination of the relative interfacial area *a* and the mass-transfer coefficients β_G and β_L, in particular, is extremely difficult. Thus, Equation (8.37) is seldom used directly; instead empirical correlations are given for the transfer units [80].

Evaluation of Equation (8.34) for different values of N_G and N_L is shown in Figure 79. The number of vapor transfer units N_G is in the range of ca. 0.5 to 2, whereas the number of liquid transfer units N_L varies more widely from 0.5 to 15. Because, in rectification, the term $m/(\dot{L}/\dot{G})$ is usually in the order of 1, point efficiencies of approximately 0.6 to 0.9 are obtained.

Figure 79. Standard values for the gas point efficiency E_{OG}
Values calculated from Equations (8.35) and (8.36): a) $N_G = 2$, $N_L = 15$; b) $N_G = 2$, $N_L = 2$; c) $N_G = 1$, $N_L = 1$; d) $N_G = 0.5$, $N_L = 0.5$
Experimental data: e) Distillation; f) Vacuum distillation; g) Absorption $\eta_L = 10-20$ cP; h) Absorption of carbon dioxide in water; i) Desorption of oxygen from water

Mass-Transfer Coefficients. The mass-transfer coefficients in the vapor, β_G, and in the liquid, β_L, can be estimated by assuming nonsteady mass transfer:

$$\beta_G = \sqrt{\frac{4}{\pi} \cdot \frac{D_G}{\tau}} \text{ and } \beta_L = \sqrt{\frac{4}{\pi} \cdot \frac{D_L}{\tau}} \tag{8.38}$$

where D_G and D_L are the diffusion coefficients of the vapor and liquid, respectively. Determination of the contact time τ is difficult. According to [75], it is equivalent to the lifetime of the interface in the two-phase layer. Because the interface is produced by the vapor penetrating the liquid, it is simultaneously the residence time of the vapor in the two-phase layer. Thus the same value is obtained for the contact time τ in both the liquid and the vapor phases. Hence, the mass-transfer coefficient in the vapor is

$$\beta_G = \sqrt{\frac{4}{\pi} \cdot \frac{D_G}{h_f} \cdot \frac{w_G}{\varepsilon_G}} \tag{8.39}$$

where w_G is the superficial gas velocity, h_f is the height of the froth layer, and ε_G is the vapor porosity. Analogously, the mass-transfer coefficient in the liquid is

$$\beta_L = \sqrt{\frac{4}{\pi} \cdot \frac{D_L}{h_f} \cdot \frac{w_G}{\varepsilon_G}} \tag{8.40}$$

These relationships apply to the froth regime and, to a close approximation, to the drop regime, but not to the bubble regime. Substitution of Equations (8.39) and (8.40) into Equation (8.37) gives

$$N_{OG} = \frac{a\sqrt{4/\pi \cdot D_G/w_G \cdot h_f/\varepsilon_G}}{1 + m\sqrt{D_G/D_L} \cdot \hat{M}_L/\hat{M}_G \cdot \varrho_G/\varrho_L} \tag{8.41}$$

The denominator in this equation takes into account additional mass-transfer resistance in the liquid phase; it contains only system properties.

Whereas in the basic relationship (Eq. 8.37), the overall vapor mass-transfer units N_{OG} are directly proportional to the height of the two-phase froth layer h_f and inversely proportional to the vapor velocity w_G, a proportionality to the square root of these parameters is obtained here; this agrees well with observed behavior.

8.3. Dimensioning of Packed Columns

The majority of packed columns use random packings composed of individual particles. Some of the more important packings are shown in Figure 80). The flow rate and the separation efficiency of the column are directly dependent on particle shape. Randomly dumped packings

Figure 80. Common random column packings
Ceramic packings are shown in the top row, metal packings in the middle row, and plastic packings in the bottom row.

should be as homogeneous as possible; bridging and large cavities between particles should be avoided. The particles should be sufficiently stable and should form a large packing surface with a low pressure drop. The particle size used depends on column diameter; depending on particle shape, it should not exceed 1/10 to 1/30 of the column diameter. Most particles are made of ceramics or metals, but plastics are being used increasingly. Characteristics of the most important packings compiled in Table 2.

The use of structured column packing dates from the 1960s. These packings provide a homogeneous bed structure (Fig. 81). They are especially especially useful, above all in vacuum columns. Sheet metal and plastic packings are being used increasingly. Characteristics of the most important structured packings are given in Table 3.

Figure 81. Element of a structured packing (Sulzer Mellapak) constructed to fit through the manway of a large-diameter column

Column calculations are carried out by representing the different packings with simple geometric models, which are usually parallel tubes or beds of spheres. The model structure is chosen so that it has the same ratio of surface area to volume (a) and the same porosity ε as the actual packing. If a bed-of-spheres model is assumed,

$$a = \frac{A}{V} = \frac{z \cdot d^2 \cdot \pi}{V} \tag{8.42}$$

where A is the surface area of the packing, V the bed volume, z the number of "model" spheres, and d their diameter. Furthermore,

$$\varepsilon = \frac{V - V_{\mathrm{sp}}}{V} = 1 - \frac{z}{V} \cdot \frac{d^3 \cdot \pi}{6} \tag{8.43}$$

where V_{sp} is the volume occupied by the spheres.

By eliminating the number of spheres z, the following equation is obtained:

$$d = \frac{6 \cdot (1 - \varepsilon)}{a} \tag{8.44}$$

Because a (the surface area relative to the volume) and ε (the porosity) are known for the actual model, the diameter of the model sphere can be determined by using Equation (8.44). The porosities of modern packings are so large that the spheres in the model structure do not touch each other.

8.3.1. Operating Region of Packed Columns

The permitted operating region of packed columns is depicted in Figure 82; the vapor load $\dot{V}_{\mathrm{G}}/A_{\mathrm{c}}$ is plotted against the liquid load $\dot{V}_{\mathrm{L}}/A_{\mathrm{c}}$ (A_{c} is the cross-sectional area of the column). The operating region of packed columns differs considerably from that of plate columns (cf. Fig. 70). In packed columns, the vapor load can be reduced to extremely small values, but the liquid load must be maintained within a defined range. This difference influences the choice of apparatus.

Figure 82. Operating region of a packed column

Two principal mechanisms limit the gas and liquid flow rates: flooding and wetting.

Flooding. The *flooding boundary* is an absolute boundary that cannot be crossed under any circumstances. At the flooding point, the countercurrent flow of vapor and liquid in the column breaks down. The liquid builds up in the packing and is pushed upward by the vapor. A froth layer can arise above the packing after the flood point has been reached. The pressure drop of the vapor increases tremendously at the flood point. Determination of the flood point is discussed in Section 8.3.2.

Wetting. In contrast to plate columns, packed columns require a minimum liquid load to ensure sufficient mass transfer. Below this minimum value, only a very small part of the column is wetted, and liquid and vapor are no longer in intimate contact. This results in a considerable drop in separating efficiency. The minimum liquid load $w_{\mathrm{L,\,min}}$ can be calculated from

$$w_{\mathrm{L,min}} = 7.7 \times 10^{-6} \left(\frac{\varrho_{\mathrm{L}} \cdot \sigma^3}{\eta_{\mathrm{L}}^4 \cdot g} \right)^{2/9} \cdot \left(\frac{g}{a} \right)^{1/2} \tag{8.45}$$

where ϱ_L is the liquid density, σ the surface tension, g the acceleration due to gravity, η_L the liquid viscosity, and a the relative surface area of the packing [81]. In practice, minimum liquid loads for dumped packings are $10\,m^3\,m^{-2}\,h^{-1}$ for aqueous systems and $5\,m^3\,m^{-2}\,h^{-1}$ for organic systems. Columns with structured packings can be operated in an organic medium with liquid amounts as small as $0.2\,m^3\,m^{-2}\,h^{-1}$ [64].

8.3.2. Two-Phase Flow in Packed Columns

A packed column allows a pure countercurrent flow of liquid and vapor streams. The liquid trickles downward over the surface of the packing in the form of rivulets or films. Considerable drop formation can also occur within the bed if a large packing size is used.

Pressure Drop. Flow through a particle bed is a basic step of multiphase flow processes that occur, for example, in fixed beds, pneumatic and hydraulic conveying, and fluidized beds. A common principle is involved, namely, flow around a single particle in the presence of neighboring particles. Fluidized beds are more suitable for investigating this basic process than fixed beds because the porosity of the fluidized bed can be varied more widely.

RICHARDSON and ZAKI have developed the following relationship for homogeneous fluidized beds [82]:

$$w_s/w_0 = \varepsilon^n \tag{8.46}$$

where w_0 is the terminal velocity of a single particle, w_s is the superficial velocity of the vapor required to fluidize a swarm of particles, and ε is the porosity. The exponent n is a function of the Reynold's number of a single particle Re_0, as shown in Figure 83. If the influence of porosity is expressed in terms of the friction factors for a swarm of particles ζ_s and a single particle ζ_0, the following expression is obtained:

$$\zeta_s/\zeta_0 = \varepsilon^{-4.65} \tag{8.47}$$

This equation is equivalent to Equation (8.46) for the entire range of Reynold's numbers, as shown in Figure 83.

Figure 83. Correlation of the exponent n as defined by RICHARDSON and ZAKI (Eq. 8.46) with the Reynold's number of a single particle Re_0 in a homogeneous fluidized bed [82]
$Re_0 = w_0 d/\nu$, where w_0 is the superficial particle velocity, d its diameter, and ν the kinematic viscosity.
a) $n = 4.65$; b) $n = 4.35/Re_0^{0.03}$; c) $n = 4.45/Re_0^{0.1}$; d) $n = 2.39$; e) $\zeta_s/\zeta_0 = \varepsilon^{-4.65}$ (Eq. 8.47)

The following expression holds for the pressure drop Δp in the fluidized bed:

$$\Delta p \cdot A_c = H \cdot A_c \cdot (1-\varepsilon) \cdot \Delta\varrho \cdot g \tag{8.48}$$

where H is the height of the packing, A_c the cross-sectional area of the column, $\Delta\varrho$ the density difference, and g the acceleration due to gravity. For a single particle in the bed,

$$\frac{d^2\pi}{4} \cdot \zeta_s \cdot \frac{\varrho_G}{2} w_G^2 = \frac{d^3\pi}{6} \cdot \Delta\varrho \cdot g \tag{8.49}$$

where w_G is the superficial vapor velocity. Elimination of $\Delta\varrho \cdot g$ and use of Equation (8.47) give

$$\frac{\Delta p}{H} = \frac{3}{4} \cdot \zeta_0 \cdot \frac{1-\varepsilon}{\varepsilon^{4.65}} \cdot \varrho_G \cdot \frac{w_G^2}{d} \tag{8.50}$$

This equation can also be applied to fixed beds. It differs considerably from the commonly used Ergun equation in the improved porosity term $(1-\varepsilon)/\varepsilon^{4.65}$ [83]:

$$\frac{\Delta p}{H} = \zeta_E \left(\frac{1-\varepsilon}{\varepsilon^3}\right) \varrho_G \cdot \frac{w_G^2}{d} \tag{8.51}$$

The improved term in Equation (8.50) enables determination of the pressure drop in a particle bed from the friction factor ζ_0 of a single particle. The Ergun equation requires utilization of a different packing friction factor ζ_E which bears no relation to the friction factor of the single particle.

Figure 84 shows a correlation of the friction factor ζ_0 and the Reynold's number for the most

important packings. The curves can be correlated by using the following equation:

$$\zeta_0 = \frac{C_1}{Re} + \frac{C_2}{\sqrt{Re}} + C_3 \tag{8.52}$$

where C_1, C_2, and C_3 are constants; for values, see Table 4.

Table 4. Constants for calculating the constants in Equation (8.52)

Pressure Drop. As shown in Figure 85, the pressure drop is always larger in an irrigated column (curves b – f) than in a dry column (curve a). The liquid flowing through the column changes the bed structure due to holdup liquid in the bed, which is defined as

$$h = V_L/V \tag{8.53}$$

where V_L is the liquid volume and V the bed volume. The holdup decreases the porosity ε', increases the particle diameter d', and changes the friction factor ζ_0' (the prime indicates the irrigated column).

Figure 85. Pressure drop Δp in a stacked packing composed of 25-mm metal Bialecki rings (porosity 0.94) as a function of vapor (w_G) and liquid (w_L) loads [84]
Liquid velocity w_L, m/h: a) 0; b) 10; c) 20; d) 40; e) 60; f) 80
Measurements were made using air – water at 20 °C and 0.1 MPa in a column with a packing height of 1.5 m and a diameter of 0.15 m.

The porosity ε' of the irrigated bed can be expressed as

$$\varepsilon' = \varepsilon - h \text{ or } \varepsilon' = \varepsilon \cdot (1 - h/\varepsilon) \tag{8.54}$$

The change in particle diameter can be formulated by assuming that the liquid is present mainly as a film or rivulet on the particles. If the number of particles is the same in irrigated and dry beds, then

$$\frac{1-\varepsilon'}{d'^3} = \frac{1-\varepsilon}{d^3} \tag{8.55}$$

Substituting Equation (8.54) yields

$$d' = d\left[\frac{1-\varepsilon\cdot(1-h/\varepsilon)}{1-\varepsilon}\right]^{1/3} \tag{8.56}$$

Liquid holdup in the packing has a negligible effect on particle shape. Hence, Equation (8.52) for the friction factor can also be applied to irrigated packings. However, the increased particle diameter d' leads to an increased Reynold's

number for the vapor and thus a lower friction factor ζ_0 (Fig. 84). If the Reynold's number is held within a narrow range, Equation (8.52) can be simplified to

$$\zeta_0 \approx Re^c \tag{8.57}$$

where $c = \frac{1}{\zeta_0}\left(-\frac{C_1}{Re} - \frac{C_2}{2\sqrt{Re}}\right)$. The exponent c lies between the limits 0 (fully turbulent flow) and 1 (laminar flow). Thus,

$$\zeta_0' = \zeta_0 \cdot (d'/d)^c \tag{8.58}$$

Using Equation (8.56) gives

$$\zeta_0' = \zeta_0 \left[\frac{1-\varepsilon\cdot(1-h/\varepsilon)}{1-\varepsilon}\right]^{c/3} \tag{8.59}$$

Thus, the pressure drop in the irrigated packing Δp_{irr} can be calculated from Equation (8.50) which applies to a nonirrigated packing:

$$\frac{\Delta p_{\mathrm{irr}}}{H} = \frac{3}{4}\cdot\zeta_0'\cdot\frac{1-\varepsilon'}{\varepsilon'^{4.65}}\cdot\varrho_{\mathrm{G}}\cdot w_{\mathrm{G}}^2/d' \tag{8.60}$$

where H is the packing height, ϱ_{G} the vapor density, and w_{G} the superficial vapor velocity.

A comparison of experimental values obtained for two dumped packings and one structured packing with values calculated by using the above equation is shown in Figure 86.

Equation (8.61) does not contain a packing-specific parameter. The first term accounts for porosity-dependent changes, a fact that has been corroborated by experimental data.

The second term of Equation (8.61) is very similar to the relationship derived by BEMER and KALIS [85]:

$$\frac{\Delta p_{\mathrm{irr}}}{\Delta p_{\mathrm{d}}} = \left(1 - \frac{h/\varepsilon}{2\cdot\Phi\cdot x^{5/3}}\right)^{-5} \tag{8.62}$$

where Φ and x are empirical constants that depend on the shape of the packing. Equation (8.62) is often used with an empirical constant C_{h} which also depends on the shape of the packing and must be determined empirically [86], [87]:

$$\frac{\Delta p_{\mathrm{irr}}}{\Delta p_{\mathrm{d}}} = (1 - C_{\mathrm{h}}\cdot h)^{-5} \tag{8.63}$$

Figure 86. Pressure drop in irrigated packings Δp_{irr} as a function of liquid holdup h
Curves indicate values calculated with Equation (8.61). Symbols indicate experimental values [84], [86]: Bialecki rings (●), porosity $\varepsilon = 0.94$; Gempak 2A (×), $\varepsilon = 0.93$; and Raschig rings (■), $\varepsilon = 0.70$.

The pressure drop in the irrigated packing can be conveniently related to the pressure drop in the nonirrigated (dry) packing Δp_{d}:

$$\frac{\Delta p_{\mathrm{irr}}}{\Delta p_{\mathrm{d}}} = \left[\frac{1-\varepsilon\cdot(1-h/\varepsilon)}{1-\varepsilon}\right]^{(2+c)/3} [1-h/\varepsilon]^{-4.65} \tag{8.61}$$

Figure 87. Liquid holdup h in a dumped packing composed of 25-mm Bialecki rings, as a function of vapor and liquid loads [84]
Liquid velocity w_{L}, m/h: a) 2.8; b) 5; c) 10; d) 20; e) 40; f) 60; g) 80
Measurements were made using air – water at 20 °C and 0.1 MPa in a column with a packing height of 1.5 m and a diameter of 0.15 m.

Figure 88. Dependence of the liquid holdup h_0 below the loading point on the Froude number of the liquid Fr_L for random and structured packings

The straight line indicates values calculated with Equation (8.64), $h_0 = 0.555 \cdot Fr_L^{1/3}$. The porosities ($\varepsilon$) and relative surface areas (a) of the different packings are as follows:
Random ceramic packings: Intalox saddles (△), $\varepsilon = 0.73$, $a = 255\,m^{-1}$ [88]; Pall rings (⊕), $\varepsilon = 0.78$, $a = 120\,m^{-1}$ [88]; Raschig rings (▲), $\varepsilon = 0.70$, $a = 300\,m^{-1}$ [86].
Random metal packings: Bialecki rings (∗), $\varepsilon = 0.94$, $a = 255\,m^{-1}$ [84]; Pall rings (+), $\varepsilon = 0.935 - 0.952$, $a = 360 - 100\,m^{-1}$ [88].
Random plastic packings: NSW rings (□), $\varepsilon = 0.96$, $a = 90\,m^{-1}$ [88]; Pall rings (○—), $\varepsilon = 0.92$, $a = 110\,m^{-1}$ [88]; Hiflow (○), $\varepsilon = 0.94$, $a = 110\,m^{-1}$ [88].
Structured metal packings: Mellapack (●), $\varepsilon = 0.96$, $a = 250\,m^{-1}$ [88]; Gempack 230 A2T (■), $\varepsilon = 0.977$, $a = 202\,m^{-1}$ [88].

Liquid Holdup. An important factor for two-phase flow in packed columns is the liquid holdup h (defined in Eq. 8.53) in the wet packing. Typical experimental curves for the holdup h in Bialecki ring packing at various gas and liquid loads are shown in Figure 87 [84]. Two regions can be distinguished: (1) a low vapor-load region in which the holdup h depends solely on the liquid load and (2) a high vapor-load region in which h depends on both the liquid and the vapor loads. The transition between these two regions occurs at the loading point.

Experimental data for h_0, the holdup below the loading point, are presented in Figure 88. These data can be correlated by using the following equation:

$$h_0/\varepsilon = 0.555 \cdot Fr_L^{1/3}, \text{ with } Fr_L = \frac{w_L^2 \cdot a}{g \cdot \varepsilon^{4.65}} \qquad (8.64)$$

where Fr_L is the Froude number of the liquid, w_L the superficial liquid velocity, a the relative surface area of the packing, and ε its porosity. This correlation does not account for any liquid properties and is applicable only to air and water. However, the holdup also depends on the liquid viscosity η_L [89] and the interfacial tension σ [90], [91]. These results have been correlated, but the correlation applies only to Raschig rings with a maximum diameter of 25 mm [92].

Figure 89. Liquid holdup in a dumped packing composed of 25-mm Bialecki rings (metal) as a function of the pressure drop in the irrigated packing Δp_{irr}
Liquid velocity w_L, m/h: a) 80; b) 60; c) 40; d) 20; e) 10

The liquid holdup h above the loading point is further influenced by both the liquid and the vapor loads. Figure 87 shows that as the absolute values of the liquid holdup h increase, increas-

ingly smaller vapor loads become effective. If the liquid holdup h is plotted against the pressure drop of the vapor, $\Delta p_{\mathrm{irr}}/(H \cdot \varrho_{\mathrm{L}} \cdot g)$, instead of against the vapor velocity w_{G}, a uniform increase is obtained (Fig. 89). The following relationship is deduced from Figure 89:

$$h = h_0 \left[1 + 20 \left(\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} \right)^2 \right] \tag{8.65}$$

where h_0 is the holdup below the loading point.

Flooding in Packed Columns. The flooding point is an important parameter in column dimensioning. It represents the column load at which the liquid can no longer flow countercurrently to the rising vapor. Liquid flow is obstructed by the high vapor load to such an extent that it collects in the bed. The flooding point is clearly indicated (e.g., in Fig. 85) by a very steep increase in the pressure drop.

Empirical correlations are available for determining the flooding point in the form of diagrams [93–96]. An example is shown in Figure 90.

Figure 90. Mersmann correlation of flooding point and pressure drop in an irrigated packing [96]
Calculated curves are shown for different values of the pressure drop in an irrigated packing, $\Delta p_{\mathrm{irr}}/(H \cdot \varrho_{\mathrm{L}} \cdot g)$: a) 0.2; b) 0.1; c) 0.05; d) 0.03; e) 0.02; f) 0.01; g) 0.005

The pressure drop in irrigated packings described above can be used to determine the flooding point. By using Equations (8.61) and (8.65), the pressure drop based on the holdup h above the loading point can be expressed as

$$\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} = \frac{\Delta p_{\mathrm{d}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} \cdot \frac{\left(1 - \varepsilon \cdot \left\{ 1 - \frac{h_0}{\varepsilon} \cdot \left[1 + 20 \left(\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} \right)^2 \right] \right\} \right)^{(2+c)/3}}{1 - \varepsilon} \cdot \left\{ 1 - \frac{h_0}{\varepsilon} \left[1 + 20 \left(\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot \mathrm{g}} \right)^2 \right] \right\}^{-4.65} \tag{8.66}$$

The flooding point is reached when an infinitely steep increase in Δp_{irr} occurs with increasing vapor load [97]. Thus, if the dry pressure drop is used as a measure of the vapor load

$$\frac{\partial \Delta p_{\mathrm{irr}}}{\partial \Delta p_{\mathrm{d}}} = \infty \text{ or } \frac{\partial \Delta p_{\mathrm{d}}}{\partial \Delta p_{\mathrm{irr}}} = 0 \tag{8.67}$$

After differentiation of Equation (8.66),

$$\left(\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} \right)_{\mathrm{f}}^{-2} - \frac{40 \frac{2+c}{3} \cdot h_0}{1 - \varepsilon + h_0 \left[1 + 20 \left(\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} \right)_{\mathrm{f}}^2 \right]} - \frac{186 \cdot h_0}{\varepsilon - h_0 \left[1 + 20 \left(\frac{\Delta p_{\mathrm{irr}}}{H \cdot \varrho_{\mathrm{L}} \cdot g} \right)_{\mathrm{f}}^2 \right]} = 0 \tag{8.68}$$

The pressure drop at which flooding occurs can be calculated from the above equation. In general, values of $\Delta p_{\mathrm{irr}}/(H \cdot \varrho_{\mathrm{L}} \cdot g)_{\mathrm{f}}$ in the range of 0.1 to 0.3 are obtained, which agree well with experimental results.

The results calculated from the pressure drop equation (Eq. 8.66) and the flooding point equation (Eq. 8.68) for Bialecki rings are plotted as a function of relative holdup h_0/ε in Figure 91. Agreement with experimentally determined flooding points is excellent. The representation in Figure 91 is very similar to the flooding point diagram shown in Figure 90; the ordinate and parameters are identical, but in Figure 90 the term $(Fr^2/Re)^{1/3}$ is used as the abscissa. This term gives a relatively good correlation for the holdup h_0, within a certain range of liquid properties. However, the surface tension σ can also be expected to have some effect [90], [91].

Figure 91. Flooding boundary and pressure drop in an irrigated packing composed of 25-mm Bialecki rings (metal) Open circles indicate experimental values [84]. Calculated curves (Eqs. 8.66 and 8.68) are shown for different values of the pressure drop in an irrigated packing, $\Delta p_{\mathrm{irr}}/(H\cdot\varrho_{\mathrm{L}}\cdot g)_{\mathrm{f}}$: a) 0.3; b) 0.2; c) 0.1; d) 0.06; e) 0.04; f) 0.02; g) 0.01; h) 0.006; i) 0.004; j) 0.002

The decisive factor in calculating the flooding point and the pressure drop in an irrigated column packing is the liquid holdup h_0. Published data (usually for air – water) are not sufficient to provide a reliable equation for this; data at low interfacial tensions and viscosities, which are typical of rectification, are lacking.

8.3.3. Calculation of Mass Transfer in Packed Columns

Principles. The calculation of mass transfer in a packed column is based on the assumption that both vapor and liquid move through the column bed in a type of plug flow. This means that back-mixing in the axial direction is not allowed. Furthermore, both phases must be uniformly distributed over the mass-transfer area A and throughout the packed height H. By using the transfer-unit concept, the following relationship is obtained (cf. Section 4.1.2):

$$\mathrm{d}N_{\mathrm{OG}}=K_{\mathrm{OG}}/\dot{G}\cdot\mathrm{d}A \tag{8.69}$$

When $\mathrm{d}A=\mathrm{d}H\cdot A_{\mathrm{c}}\cdot a$ (A_{c} is the cross-sectional area of the column and a is the relative surface area of the packing), the differential height of the packing is

$$\mathrm{d}H=\mathrm{d}N_{\mathrm{OG}}\cdot\frac{\dot{G}}{K_{\mathrm{OG}}\cdot A_{\mathrm{c}}\cdot a} \tag{8.70}$$

The second term of this equation is defined as the height of an overall gas-phase transfer unit H_{OG}:

$$H_{\mathrm{OG}}=\frac{\dot{G}}{K_{\mathrm{OG}}\cdot A_{\mathrm{c}}\cdot a} \tag{8.71}$$

The overall gas-phase mass-transfer coefficient K_{OG} is calculated from the coefficients of the phases involved, K_{G} and K_{L}:

$$\frac{1}{K_{\mathrm{OG}}}=\frac{1}{K_{\mathrm{G}}}+\frac{m}{K_{\mathrm{L}}} \tag{8.72}$$

where m is the slope of the equilibrium curve on the $y-x$ diagram. Furthermore,

$$K_{\mathrm{G}}=\beta_{\mathrm{G}}\cdot\varrho_{\mathrm{G}}/\hat{M}_{\mathrm{G}}\ \text{and}\ K_{\mathrm{L}}=\beta_{\mathrm{L}}\cdot\varrho_{\mathrm{L}}/\hat{M}_{\mathrm{L}} \tag{8.73}$$

Simple rearrangement gives

$$\frac{\dot{G}}{A_{\mathrm{c}}}=w_{\mathrm{G}}\cdot\varrho_{\mathrm{G}}/\hat{M}_{\mathrm{G}} \tag{8.74}$$

By using Equations (8.72) – (8.74), the height of a mass transfer unit can be expressed as

$$H_{\mathrm{OG}}=\frac{w_{\mathrm{G}}}{a\cdot\beta_{\mathrm{G}}}\cdot\left(1+m\frac{\beta_{\mathrm{G}}}{\beta_{\mathrm{L}}}\cdot\frac{\hat{M}_{\mathrm{L}}}{\hat{M}_{\mathrm{G}}}\cdot\frac{\varrho_{\mathrm{G}}}{\varrho_{\mathrm{L}}}\right) \tag{8.75}$$

Equation (8.75) contains three unknown terms specific to the apparatus: the volumerelated interfacial area a, the mass-transfer coefficient β_{G} in the gas, and the mass-transfer coefficient β_{L} in the liquid. Standard values for the height of one transfer unit are in the range $H_{\mathrm{OG}}=0.2-0.3$ m for structured packing. Values for randomly dumped packing depend strongly on the column diameter D_{c} because the particle size and, consequently, the surface area of the packing bear a definite relation to the column diameter. The following value is often employed:

$$H_{\mathrm{OG}}\approx(0.5-1)\cdot D_{\mathrm{c}} \tag{8.76}$$

Thus, small laboratory columns produce excellent separation, whereas industrial columns with large diameters are much less effective.

Determination of Unknowns. Determination of the unknown factors in Equation (8.75) is discussed in the following material.

The *mass-transfer area A* in a packing is related to the bed volume V to give the volume-related mass-transfer area of the packing a:

$$a = A/V \tag{8.77}$$

The liquid generally moves in rivulets over the surface of the bed, but complete wetting of the particles usually does not occur. Hence, the mass-transfer area is generally smaller than the surface area of the packing. Experiments on the movement of rivulets on plates have provided the following relationship for the wet surface area a_{irr} [98], [99]:

$$a_{\mathrm{irr}} = 0.76 \cdot w_{\mathrm{L}}^{0.4} \cdot \nu_{\mathrm{L}}^{0.2} \cdot \left(\frac{a^2}{\varepsilon}\right)^{0.6} \cdot \left(\frac{\varrho_{\mathrm{L}}}{\sigma \cdot g}\right)^{0.15} / (1 - 0.93 \cdot \cos\theta) \tag{8.78}$$

The ability of different liquids to wet various packing materials is expressed in terms of the contact angle θ. Values of θ are given in [99]. The effective interface area for mass transfer a_{e} is calculated as follows:

$$a_{\mathrm{e}} = F_{\mathrm{a}} \cdot a_{\mathrm{irr}} \tag{8.79}$$

where $F_{\mathrm{a}} = 52 \cdot d^{1.1}$ for ceramic materials
$F_{\mathrm{a}} = 138 \cdot d^{1.1}$ for plastic materials
The proportionality factor F_{a} takes into account the additional influences of packing size and material.

The *gas-phase mass-transfer coefficient* β_{G} can be determined with the following equation [100]:

$$\beta_{\mathrm{G}} = C_{\beta\mathrm{G}} \left(\frac{w_G^2 \cdot D_{\mathrm{G}}^2}{d_{\mathrm{N}} \cdot \nu_{\mathrm{G}}}\right)^{1/3} \tag{8.80}$$

where $C_{\beta\mathrm{G}}$ is a constant, w_{G} is the superficial gas velocity, D_{G} is the vapor diffusion coefficient, d_{N} is the nominal diameter of the packing, and ν_{G} is the kinematic viscosity. This relationship is applicable when

$$Re_{\mathrm{G}} = \frac{\varrho_{\mathrm{G}} \cdot w_{\mathrm{G}} \cdot d_{\mathrm{N}}}{\eta_{\mathrm{G}} \cdot (1 - \varepsilon)} > 1000 \tag{8.81}$$

Values of the constant $C_{\beta\mathrm{G}}$ for ceramic and metal packings are 0.673 (beads), 0.417 (Raschig rings), and 0.73 (saddles); this is purely a shape factor that is independent of particle size.

According to a model developed by Zech [101], a nonsteady mass-transfer mechanism exists in the liquid. A defined liquid element is located on the phase interface as long as the film or rivulet flows over a single packing element. At the point of contact with the next element, the liquid is completely mixed and a new liquid surface is formed. This new interface, in turn, exists only as long as the liquid flows over this particle and so on. An equation for the *liquid mass-transfer coefficient* based on this model has been derived [99]:

$$\beta_{\mathrm{L}} = 0.86 \left(\frac{6 \cdot D_{\mathrm{L}}}{\pi \cdot d_{\mathrm{N}}}\right)^{1/2} \cdot \left[\frac{w_{\mathrm{L}}^{1.2} \cdot g \cdot \sigma_{\mathrm{L}}^{0.3} \cdot \varepsilon^{1.2} 1/3}{\nu_{\mathrm{L}}^{1.4} \cdot \varrho_{\mathrm{L}}^{0.3} \cdot a^{2.4}} (1 - 0.93 \cdot \cos\theta)^2\right]^{1/6} \tag{8.82}$$

Problems. The formulas for calculating the mass-transfer efficiency of packed columns, described above, are not totally satisfactory. One reason is that the phase interface is difficult to determine. The large number of equations developed for this purpose do not show a uniform trend with respect either to the order of magnitude of the interface or to the dependence on operational, material, or geometric parameters. Even the determination of mass-transfer coefficients, especially in the liquid, is somewhat uncertain.

The main reason for the persistent inaccuracy in calculating the mass-transfer efficiency of packed columns is the assumption that plug flow occurs within the packing. The associated assumption of uniform liquid flow rate over the column cross section is certainly not valid in large-scale industrial columns. Uniform distribution of liquid over the entire flow area becomes increasingly difficult to achieve at large column diameters (maldistribution).

Liquid maldistribution in a column of 3.6-m packed height and 0.63-m diameter is shown in Figure 92, which employs the technique described for plate columns in Figure 74 [102]. The longitudinal liquid isotherms can be interpreted as lines of equal liquid residence time. These isotherms should be horizontal straight lines if plug flow occurs. Figure 92 A shows that despite excellent initial liquid distribution, significant

deviations from plug flow occur with increasing column length. Uneven liquid distribution is observed not only at the edges of the column, but also within the column; this is caused primarily by a slight inhomogeneity of the packing.

Figure 92. Liquid maldistribution in a column of 3.6-m packed height and 0.63-m diameter packed with 35-mm Pall rings [102]
The indicated liquid isotherms should be horizontal straight lines for uniform liquid flow through the cross-sectional area of the column.
A) Multiple feed entry points, $\bar{H}_{OG} = 0.44$ m; B) Single feed entry point, $\bar{H}_{OG} = 0.67$ m

Deviations from plug flow are especially marked when liquid is fed in at a single point (Fig. 92 B). The initial liquid distribution is poor and changes only slightly along the length of the column. Thus, unequal amounts of vapor and liquid come in contact with each other along the cross-sectional area of the column. In regions of small liquid load, phase equilibrium can be reached relatively rapidly and these zones no longer contribute to the separation efficiency of the column (pinch point).

Detailed theoretical studies have shown that even if the initial liquid distribution is good, a substantial part (up to 50 %) of the possible separation efficiency is lost as a result of maldistribution [102]. Maldistribution is especially troublesome in purely countercurrent columns because the effects accumulate over the entire column height. In plate columns, however, these effects are restricted to a single plate because the liquid is mixed in the next downcomer. Thus, plate columns are especially suitable for large column diameters. Large-diameter packed columns can be employed only if special precautions are taken to ensure good liquid distribution over the flow area.

s	solid, sublimation, surface
v	vaporization

1. Introduction

The term sublimation refers strictly to the phase change:
Solid → Vapor
when the transformation occurs without intervention of the liquid phase. In industrial applications, however, the term sublimation usually includes the reverse process, i.e., condensation (desublimation):
Solid → Vapor → Solid
In practice, vaporization of a substance from the liquid state is sometimes desirable; therefore, the complete series of phase changes in an industrial sublimation process can be:
Solid → Liquid → Vapor → Solid
Appearance of the liquid phase is specifically prohibited on the condensation side of the process: the supersaturated vapor must condense directly to the crystalline solid state.

Common organic compounds that can be purified by sublimation include:

2-aminophenol	isophthalic acid
anthracene	naphthalene
anthranilic acid	2-naphthol
anthraquinone	phthalic anhydride
benzanthrone	phthalimide
benzoic acid	pyrogallol
1,4-benzoquinone	salicylic acid
camphor	terephthalic acid
cyanuric chloride	thymol

Amenable elemental and inorganic substances include:

aluminum chloride	iron(III) chloride
arsenic	magnesium
arsenic(III) oxide	molybdenum trioxide
calcium	sulfur
chromium(III) chloride	titanium tetrachloride
hafnium tetrachloride	uranium hexafluoride
iodine	zirconium tetrachloride

In addition, the sublimation of ice in freeze drying has become an important operation in the biological and food industries (→ Drying of Solid Materials, Chap. 2.5.; → Foods, 2. Technology, Chap. 2.4.2.).

Reviews of the industrial applications of sublimation techniques are given in [1–6], of the principles underlying vaporization and condensation in [7], and of techniques for growing crystals from the vapor phase in [8, 23] (see also → Crystal Growth, Chap. 8.).

2. Phase Equilibria

A sublimation process is controlled primarily by the conditions under which phase equilibria occur in a single-component system, i.e., in the sublimable substance. The phase diagram of a simple one-component system shown in Figure 1 depicts the equilibria between solid, liquid, and gaseous states. The diagram is divided into three zones by (1) the *sublimation curve* AT, which records the vapor pressure of the solid, (2) the *vaporization curve* TB, which records the vapor pressure of the liquid, and (3) the *fusion curve* TC, which records the effect of pressure on the melting point. In virtually all one-component systems, the fusion curve slopes to the right, i.e., in the direction of increasing temperature, indicating that the melting point of the solid phase increases with pressure. However, water – an extremely important one-component system – is very unusual in that increasing pressure decreases the melting point of ice.

Figure 1. Phase diagram for a single-component system

The slopes of the sublimation, vaporization, and fusion curves in Figure 1 can be expressed quantitatively by the Clapeyron equation:

$$\left(\frac{\mathrm{d}P}{\mathrm{d}T}\right)_{\mathrm{sub}} = \frac{\lambda_{\mathrm{s}}}{T\,(v_{\mathrm{g}} - v_{\mathrm{s}})} \tag{1}$$

$$\left(\frac{\mathrm{d}P}{\mathrm{d}T}\right)_{\mathrm{vap}} = \frac{\lambda_{\mathrm{v}}}{T\,(v_{\mathrm{g}} - v_{\mathrm{l}})} \tag{2}$$

$$\left(\frac{\mathrm{d}P}{\mathrm{d}T}\right)_{\mathrm{fus}} = \frac{\lambda_{\mathrm{f}}}{T\,(v_{\mathrm{l}} - v_{\mathrm{s}})} \tag{3}$$

where P is the vapor pressure, T the absolute temperature, and v_{s}, v_l, and v_{g} are the molar volumes of the solid, liquid, and gas phases, respectively. The latent heats (enthalpies) of sublimation, vaporization, and fusion (λ_{s}, λ_{v}, and λ_{f}, respectively) are related at a given temperature by

$$\lambda_{\mathrm{s}} = \lambda_{\mathrm{v}} + \lambda_{\mathrm{f}} \tag{4}$$

Analysis of sublimation–desublimation is often hindered by the scarcity of published physical data. If, however, only two reliable values of vapor pressure are available, a considerable amount of information can be derived from the Clausius–Clapeyron equation:

$$\ln\left(\frac{P_1}{P_2}\right) = \frac{\lambda_{\mathrm{v}}\,(T_1 - T_2)}{RT_1T_2}$$

where the gas constant $R = 8.314\,\mathrm{J\,mol^{-1}\,K^{-1}}$.

For example, the vapor pressures of naphthalene at 190 and 160 °C are 780 and 220 Pa, respectively. Equation (5) can be used to estimate a mean value of λ_{v}. If the assumption is made that λ_{v} does not vary greatly over the temperature range considered, λ_{v} can then be used to estimate the vapor pressure at some other temperature, e.g., 120 °C. Thus,

$$\ln\left(\frac{780}{220}\right) = \frac{\lambda_{\mathrm{v}}\,(463 - 433)}{8.314 \times 463 \times 433}$$

which gives $\lambda_{\mathrm{v}} = 70\ 340$ J/mol

and

$$\ln\left(\frac{220}{P}\right) = \frac{70340\,(433 - 393)}{8.314 \times 433 \times 393}$$

which gives $P = 30$ Pa at 120 °C

The three curves in Figure 1 intersect at the *triple point* T; this represents the temperature and pressure at which the solid, liquid, and gas

phases coexist in equilibrium. The position of the triple point in the phase diagram is of the utmost importance in sublimation–desublimation processes. If it occurs at a pressure above atmospheric, the solid cannot melt under normal atmospheric conditions, and true sublimation (i.e., the transition solid → vapor) is easily achieved. For example, the triple point for carbon dioxide occurs at − 57 °C and 500 kPa; thus, liquid CO_2 is not formed when solid CO_2 is heated at atmospheric pressure (101.3 kPa), and the solid simply vaporizes. If the triple point occurs at a pressure less than atmospheric, however, certain precautions are necessary if the phase changes solid → vapor (sublimation) and vapor → solid (desublimation) are to be controlled. For example, because the triple point for water is 0.01 °C and 0.6 kPa, ice melts when it is heated above 0 °C at atmospheric pressure. For ice to sublime, both the temperature and the pressure must be kept below the triple-point values.

From the industrial point of view, desublimation (crystallization) is the most important step; this means that the equipment responsible for condensation must operate below the triple point. If the solid → liquid stage is permitted before vaporization, the operation is often called *pseudosublimation.*

Both true sublimation and pseudosublimation cycles are depicted on the phase diagram in Figure 2. For a substance with a triple point (T) at a pressure greater than atmospheric, true sublimation (i.e., solid → vapor) occurs. The complete cycle is given by path ABCDE. The original solid, represented by point A, is heated to a temperature represented by point B. The increase in vapor pressure of the substance is traced along the sublimation curve from A to B. The condensation part of the process is represented by the broken line BCDE. As the vapor passes from the vaporizer to the condenser, it may cool slightly and be diluted with an inert gas such as air. Therefore, point C, which represents a temperature and partial pressure slightly lower than point B, can be taken as the condition at the condenser inlet. After entering the condenser, the vapor is mixed with more inert gas, and the partial pressure of the substance and its temperature drop to a point D. Thereafter, the vapor cools essentially at constant pressure to the conditions represented by point E, the temperature of the condenser.

Figure 2. Phase diagram showing true sublimation (ABCDE) and pseudosublimation (AB′C′DE) cycles

When the triple point of the substance occurs at a pressure lower than atmospheric, heating may easily result in the temperature and vapor pressure of the solid exceeding triple-point conditions. The solid will then melt in the vaporizer; path AB′ represents such a process. Great care must be taken in the condensation stage; the partial pressure of the substance in the vapor stream entering the condenser must be reduced below the triple-point pressure to prevent initial condensation to a liquid. The required partial pressure reduction can be brought about by diluting the vapor with an inert gas, but the frictional pressure drop in the vapor line is often sufficient. Point C′ represents the conditions at the point of entry into the condenser; the condensation path is represented by C′DE.

Fractional Sublimation. If two or more sublimable substances form true solid solutions, their separation by fractional sublimation is theoretically possible. The phase diagram for a binary solid-solution system at a pressure below the triple-point pressures of the two components is shown in Figure 3. Points A and B represent the equilibrium sublimation temperatures of pure components A and B, respectively, at a given pressure. The lower curve represents the sublimation temperatures of mixtures of A and B, while the upper curve represents the solid-phase condensation temperatures, generally called *snow points.* Figure 4 shows that if a solid solution (e.g., point S) is partially sublimed (e.g., heated to some temperature represented by point X), the resulting vapor phase (point Y) and residual solid (point Z) contain different propor-

tions of the original components, quantified by the *mixture rule* (→ Crystallization and Precipitation). The sublimate and the residual solid may each be resubjected to this procedure; therefore, the possibility of fractionation exists. However, the practical difficulties in performing such a separation may be considerable.

Figure 3. Phase diagram for a two-component solid-solution system at a pressure below the triple points of the two components A and B

Figure 4. Fractional sublimation of two components A and B demonstrated on a solid-solution phase diagram

Experimental studies of fractional sublimation are described in [9–11]; nucleation and growth rates of organic condensates, as well as their application to the fractionation of mixed vapors, are reported in [12].

3. Vaporization and Condensation

Vaporization. The maximum theoretical vaporization rate V (kg m^{-2} s^{-1}) from the surface of a pure liquid or solid under its own vapor pressure is given by the Hertz–Knudsen equation [13], which can be derived from the kinetic theory of gases:

$$V = P_s\,(M/2\pi RT_s)^{1/2} \tag{6}$$

where P_s is the vapor pressure (in Pa), at the surface temperature T_s (in K), M is the molecular mass, and R is the gas constant (8.314 J mol^{-1} K^{-1}).

In practice, however, the actual vaporization rate may be slower than predicted by Equation (6), and a correction factor α (≤ 1), generally referred to as an evaporation coefficient, is conventionally included:

$$V = \alpha P_s\,(M/2\pi RT_s)^{1/2} = 52.2\alpha P_s\,(M/T_s)^{1/2} \tag{7}$$

A laboratory technique used to measure values of α for sublimable solid materials is described in [14]. Sublimation rates of pure solids into turbulent air streams have been successfully correlated by the Gilliland–Sherwood equation [11]:

$$d/x = 0.023Re^{0.38}Sc^{0.44} \tag{8}$$

where d is a characteristic dimension of the vaporization chamber, x is the thickness of the effective film for mass transfer at the vapor–solid interface, and Re and Sc are the dimensionless Reynolds and Schmidt numbers, respectively.

Condensation (desublimation) is generally a transient operation, in which simultaneous heat and mass transfer are further complicated by the effects of spontaneous condensation in the bulk gaseous phase [15]. Several steps, which may or may not be mutually dependent, can be involved in the condensation of a solid phase from a vapor. The first step after the creation of supersaturation in the vapor phase is nucleation. Nucleation may be homogeneous but is predominantly heterogeneous under most circumstances; it is followed by both crystal growth

and agglomeration in the formation of the final crystal product (→ Crystallization and Precipitation, → Crystallization and Precipitation, → Crystallization and Precipitation). As a rate process, the condensation of solids from vapors is less well understood than vaporization [7]. A simple laboratory technique for measuring kinetics in subliming systems is described in [16]; it has been used to compare the solid evaporation and crystal growth rates of benzophenone under comparable conditions.

The two most common ways of creating the supersaturation necessary for crystal nucleation and subsequent growth are (1) cooling via a metal surface (which can lead to either a glassy or a multicrystalline deposit that necessitates mechanical removal) and (2) dilution (e.g., with an inert gas) which, under suitable conditions, can produce a loose crystalline mass that is easy to handle.

The measurement and correlation of heat-transfer rates during condensation in a pilot plant connected to an industrial phthalic anhydride desublimation unit are described in [17]. A comprehensive study of the condensation of several sublimable materials in a fluidized bed is reported in [18]; an extensive study on heat- and mass-transfer processes in a fluidized-bed desublimation unit is summarized in [19]. A desublimation mathematical model to predict optimum cooling conditions for smooth- and fin-tube heat exchangers is proposed in [24] and comparisons are made with industrial-scale data for phthalic anhydride.

4. Sublimation Processes

Sublimation techniques can be classified conveniently into three types: simple, vacuum, and entrainer.

4.1. Simple and Vacuum Sublimation

Simple sublimation is a batchwise process in which the solid material is heated and vaporized. The resulting vapor diffuses toward a condenser, the driving force for diffusion being the partial-pressure difference between the vaporizing and condensing surfaces. The vapor path between the vaporizer (sublimer) and the condenser should be as short as possible to reduce resistance to flow. Simple sublimation has been practiced for centuries, often in very crude equipment, for the commercial production of ammonium chloride, iodine, and "flowers" of sulfur.

Vacuum sublimation is a natural development of simple sublimation, particularly if the triple-point pressure of the substance is lower than atmospheric. The transfer of vapor from the vaporizer to the condenser is enhanced by reducing the pressure in the condenser and, consequently, increasing the partial-pressure driving force. Iodine, pyrogallol, and many metals have been purified by vacuum sublimation. Exit gases from the condenser usually pass through a cyclone or scrubber to protect the vacuum equipment and minimize product loss.

4.2. Entrainer Sublimation

4.2.1. Process Description

In entrainer sublimation, an inert gas (entrainer) is blown into the vaporization chamber of a sublimer to increase the vapor flow rate to the condensing equipment and, thus, increase the yield. Air is the most commonly used entrainer, but superheated steam can be employed for substances that are relatively insoluble in water such as anthracene. If steam is used, the vapor may be cooled and condensed by direct contact with a spray of cold water. Efficient recovery of the sublimate is thus obtained, but the product is wet.

The use of an entrainer gas in a sublimation process has many desirable features. As already mentioned, it enhances the flow of vapor from the sublimer to the condenser. It also provides the heat needed for sublimation and, thus, an efficient means of temperature control. The gas can provide the dilution, if necessary, for fractional condensation at the desublimation stage. Entrainer sublimation, whether by gas flow over a static bed of solid particles or through a fluidized bed, is ideally suited to continuous operation.

The purification of salicylic acid [*69-72-7*] is a good example of the industrial use of entrainer sublimation. Air may be used as the carrier gas, but because salicylic acid can be decarboxylated in hot air, a mixture of air and CO_2 is often preferred. A batchwise process is shown in Figure 5.

A 5 – 10 vol% mixture of CO_2 in air is recycled through the plant; it passes over heater coils (b) and then over the containers (c) (bins or trays) of impure salicylic acid in the vaporizer (d). The vapor is then conducted through a series of air-cooled condensers (e), where the sublimed salicylic acid is deposited. A trap (f) removes any entrained sublimate from the gas stream before it is returned to the heater. Makeup CO_2 and air are introduced as required. The process continues until the containers are emptied of all volatile matter.

Figure 5. Entrainer batch sublimation process for the purification of salicylic acid [3]
a) Pump; b) Heater; c) Salicylic acid container; d) Vaporizer; e) Condenser; f) Trap

A general-purpose, continuous entrainer sublimation plant is shown in Figure 6. The impure feedstock is pulverized in a mill (b), if necessary, a suitable entrainer gas (e.g, hot air) blows the fine particles, which volatilize readily, into a series of separators (c) (e.g., cyclones) where nonvolatile solid impurities are removed. A filter (d) may also be located in the vapor line to remove final traces of inert, solid impurities. The vapor then passes to a series of condensers (e) from which the sublimate is subsequently discharged. Exhaust gases can be recycled or passed to the atmosphere through a cyclone or wet scrubber to recover any entrained product.

Figure 6. General-purpose continuous sublimation unit [3]
a) Heater; b) Mill; c) Separator; d) Filter; e) Condenser

The application of fluidization techniques to sublimation–desublimation processes was first proposed by MATZ with the objective of enhancing both heat and mass transfer [20]. The technique has not yet been widely adopted for large-scale commercial use, but a fluidized-bed desublimation unit operating in the United States has been reported to produce aluminum chloride at a rate of ca. 10 t/h [21].

4.2.2. Product Yield

The yield from an entrainer sublimation process can be estimated as follows. The mass flow rate G of the inert gas and the mass sublimation rate S are related by

$$G/S = \varrho_g p_g / \varrho_s p_s \tag{9}$$

where p_g and p_s are the partial pressures of the inert gas and vaporized substance, respectively, in the vapor stream, and ϱ_g and ϱ_s are their respective vapor densities. The total pressure P of the system is the sum of the partial pressures of the components:

$$P = p_g + p_s \tag{10}$$

Thus, Equation (9) can be written as

$$S = G\left(\frac{\varrho_s}{\varrho_g}\right)\left(\frac{p_s}{P - p_s}\right) \tag{11}$$

or, in terms of the molecular masses of the inert gas, M_g, and of the material being sublimed, M_s

$$S = G\left(\frac{M_s}{M_g}\right)\left(\frac{p_s}{P - p_s}\right) \tag{12}$$

The theoretical maximum yield from an entrainer sublimation process is the difference between the calculated sublimation rates corresponding to the conditions in the vaporization and condensation stages.

For example, salicylic acid ($M_s = 138$) is to be purified by entrainer sublimation with air ($M_g = 29$) at 150 °C. The vapor is fed at atmospheric pressure (101.5 kPa) to a series of condensers, the internal temperature and pressure of the last condenser being 40 °C and 100 kPa, respectively. The air flow rate is 2000 kg/h, and the pressure drop between the vaporizer and the last condenser is 1.5 kPa. The vapor pressures of salicylic acid at 150 and 40 °C are 1.44 and 0.0023 kPa, respectively. Therefore, under saturated conditions:

Vaporization stage ($P = 101.5$ kPa, $p_s = 1.44$ kPa):

$$S_v = 2000\left(\frac{138}{29}\right)\left(\frac{1.44}{101.5 - 1.44}\right) = 137\text{kg/h}$$

Condensation stage ($P = 100$ kPa, $p_s = 0.0023$ kPa):

$$S_c = 2000\left(\frac{138}{29}\right)\left(\frac{0.0023}{100 - 0.0023}\right) = 0.22\text{kg/h}$$

In this example, therefore, the loss from the condenser exit gases is only 0.22 kg/h, and the theoretical maximum yield is ca. 137 kg/h. This maximum yield is obtained, however, only if the air is saturated with salicylic acid vapor at 150 °C, and saturation is approached only if the air and salicylic acid are in contact for a sufficient period of time at the required temperature. A fluidized-bed vaporizer may allow realization of these optimum conditions, but if air is simply blown over bins or trays containing the solid, saturation will not be reached and the actual rate of sublimation will be lower than calculated. In some cases, the degree of saturation achieved may be as low as 10 % of the calculated value.

The calculated loss of product in the condenser exit gases is only a minimum value. Other losses resulting from entrainment of solids depend on the condenser design and cannot be calculated. An efficient exit-gas scrubber can, of course, minimize these losses.

4.2.3. Comparison of Entrainer Sublimation and Crystallization

An analysis of the commercial purification of naphthalene [*91-20-3*] suggests that sublimation is potentially more economical than conventional melt crystallization [6] (for a description of melt crystallization, see →Crystallization and Precipitation). A flow sheet for entrainer sublimation is given in Figure 7, and this process is compared economically with crystallization in Table 1. In the proposed sublimation method, which has not yet been scaled up to commercial size, the solid feedstock is completely va-

Figure 7. Proposed entrainer sublimation process for the purification of naphthalene [6]

porized in an entrainer gas (nitrogen) stream and then partially condensed. Heat is removed by vaporizing water at the top of the condenser (d). To prevent deposition of sublimate on vessel walls, the inner wall of the condenser is permeable and allows some of the entrainer gas to pass through. Impurities remain in the vapor stream and are subsequently condensed in the cooler (h) located after the entrainer circulation compressor (f). The impurity–wastewater stream leaving the separator (j) is washed with benzene in an extractor (k).

Table 1. Comparison of entrainer sublimation with conventional melt crystallization for the production of naphthalene [6]

Process parameter	Crystallization	Sublimation
Naphthalene content of feedstock, wt %	92.5	90.0
Naphthalene content of product, wt %	99.6	99.6
Yield of naphthalene, %	78.0	93.7
Naphthalene production rate, kg/h	1000	1000
Steam used per tonne of naphthalene, kg	200	320
Electricity used per tonne of naphthalene, kW · h	70	119
Cooling water used per ton of naphthalene, m^3	200	14
Space requirement, m^3	7500	500
Investment cost (1983), 10^6 \$	1.75	0.62

As shown in Table 1, sublimation gives a higher yield of naphthalene at a lower cost, and with a smaller space requirement, than crystallization. Although steam and electricity consumption is higher for sublimation, this is offset by a much lower cooling-water requirement.

4.3. Fractional Sublimation

As mentioned in Chapter 2, the separation of two or more sublimable substances by fractional sublimation is theoretically possible if the substances form true solid solutions. However, large-scale commercial exploitation of fractional sublimation has not yet been reported. A laboratory-scale process known as thin-film fractional sublimation has been developed and is shown schematically in Figure 8 [9]. This process has been applied successfully to the separation of volatile solid mixtures such as hafnium and zirconium tetrachlorides, 1,4-dibromobenzene and 1-bromo-4-chlorobenzene, and anthracene and carbazole. A stream of inert, nonvolatile solids (e.g., glass beads or sand) is fed to the top of a vertical fractionation column (b) and falls countercurrently to the rising supersaturated vapor. Vapor movement is facilitated by an upwardly flowing entrainer gas stream. The temperature of the incoming solids is maintained well below the snow-point temperature of the vapor. Consequently, the solids become coated with a thin film (10 μm) of sublimate, which acts as a reflux for the enriching section of the column above the feed entry point.

Figure 8. Thin-film fractional sublimation column [9]
a) Reflux condenser; b) Fractionation column; c) Vaporizer; d) Condenser

5. Sublimation Equipment

Very few standard forms of sublimation or desublimation equipment are in common use. Most industrial units, particularly on the condensation side of the process, have been developed on an ad hoc basis for a specific substance

and purpose. The most useful source of information on sublimation equipment is the patent literature, but this has the severe drawback of not indicating whether a process has been, or even can be, put into practice [4,5].

5.1. Vaporizers

A variety of vaporization units have been used or proposed for large-scale operation, depending on the manner in which the solid feedstock is to be vaporized. Examples are [4]:

1) a bed of dry solids without entrainer gas (the simplest arrangement);
2) dry solids suspended in a dense nonvolatile, liquid;
3) solids suspended in a boiling (entrainer) liquid where the entrainer gas is formed in situ;
4) entrainer gas flowing through a fixed bed of solid particles;
5) entrainer gas bubbling through molten feedstock; i.e., vaporization takes place above the triple-point pressure;
6) entrainer gas flowing through a dense phase of solid particles in a fluidized bed;
7) entrainer gas flowing through a dilute phase of solid particles (e.g., in a transfer-line vaporizer where the solid and gas phases are in concurrent flow, or in a raining solids unit where the solids and entrainer may be in countercurrent flow);
8) vacuum sublimation where the vapour phase consists essentially of the sublimate; e.g., vaporization takes place below the triple-point pressure without entrainer gas in an agitated vaporizer with large self-cleaning heat exchange surfaces [25].

5.2. Condensers

Sublimate condensers are usually large, air-cooled chambers which tend to have very low heat-transfer coefficients (generally 5–10 $W\,m^{-2}\,K^{-1}$). This is expected because sublimate deposits on the condenser walls act as an insulator. In addition, vapor velocity in the chambers is generally very low. Quenching the vapor with cold air in the chamber may increase the rate of heat removal, but excessive nucleation is likely and the product crystals will be very small. Condenser walls may be kept free of solid by using internal scrapers, brushes, and other devices. All vapor lines in sublimation units should have a large diameter, be adequately insulated, and if necessary, be provided with supplementary heating to minimize blockage due to the buildup of sublimate.

One of the main hazards of air-entrainment sublimation is the risk of fire; many substances that are considered quite safe in their normal state can produce explosive mixtures with

Figure 9. Semi-continuous DISCOTHERM B vacuum sublimation unit [26]

air. All electrical equipment should be flameproof, and all parts of the plant should be efficiently grounded (earthed) to avoid buildup of static electricity. Vacuum operation after nitrogen purging can provide a much safer environment.

The totally enclosed production unit (Fig. 9) is provided with self-cleaning heat exchange surfaces and operates semi-continuously under reduced pressure without a carrier gas. Accumulated impurities are discharged from the sublimator periodically. Batch and continuous modifications of this unit are available [26]. Sublimation units as shown in Figure 9 have been successfully applied industrially for the purification of dyestuff intermediates, anthraquinone, metal-organic compounds and pharmaceutical products with capacities from 300 – 10 000 t/a.

Figure 10. Sublimation chamber with gas-permeable walls [10]
a) Water jet; b) Inserted porous cylinder; c) Jacket; d) Product collection zone

Calculation of the density of deposited layers of sublimate, and of associated variables, as an aid towards the optimization of sublimate condenser design, is discussed in [22]. The starting point of the analysis is the assumption that the growth of sublimate layers is governed mainly by heat and mass transfer; the model is based on conditions in the diffusion boundary layer. The main process-determining factors (growth rate, mass transfer, and gas concentration) are accounted for. The derived theoretical relationship is shown to fit experimental data.

In a variant of the large-chamber desublimation condenser, the crystallization chamber is fitted with gas-permeable walls (Fig. 10) [10]. Vapor and entrainer gas are cooled by evaporation of water dispersed in the cooling space formed by the porous walls. An inert gas passes through the porous walls into the cooling space and protects the internal walls from solid deposits. Crystallization take place in the bulk vapor–gas mixture by direct contact with the dispersed water. This system has been used, for example, for partial separation of a mixture of phthalic anhydride and naphthalene by using nitrogen as the entrainer.

Fluidized-bed condensers (desublimation units) have been considered for large-scale application, although most of the published reports are concerned with laboratory-scale investigations [19].

1. Fundamentals and Fields of Application

Liquid – liquid extraction or *solvent extraction* is a separation process which is based on the different distribution of the components to be separated between two liquid phases. It depends on the mass transfer of the component to be extracted from a first liquid phase to a second one.

Definitions. The phases form definite contact areas and cannot or can only to a limited extent mix with one another on account of their properties. The phases are composed of individual substances, so-called components, and flow as liquid streams through the extractor (see Fig. 1). Phases are liquid streams that are in equilibrium with each other.

Generally, more than three components are involved in an extraction. To make the description of the problem simpler, *key components* are

defined. The *feed* to a liquid – liquid extraction is the solution that contains the components to be separated. The key component of this liquid phase (the phase from which the solute is extracted) is called A, the transferred substance (the *solute*) C. The (*extraction*) *solvent* is the liquid added to the process to extract the substance C from the feed. The solvent can be the pure component, B, but usually contains small quantities of C and A, because the solvent is usually recycled from a recovery system. The solvent phase leaving the *extractor* is the *extract.* The extract contains mainly B and the extracted component C but also small quantities of A. The *raffinate* is the liquid phase left from the feed after being contacted by the extraction solvent; it is composed mainly of A, but generally small quantities of the extracted component C and solvent B.

Comparison with Distillation. Liquid – liquid extraction has similarities with distillation. In both cases the substances to be separated have concentration ratios $\neq 1$ in the two phases. In the case of distillation the second phase (the vapor phase) is formed exclusively from the components of the initial (liquid) phase, with extraction a new substance, the (extraction) solvent, must be added to form the second (liquid) phase. The solvent enters into the material balance of the process and its behavior towards the substances to be separated is decisive for the separation process.

Generally, the extracted substance is separated from the solvent by distillation and the solvent B is recycled to the extractor. Sometimes the selective action of the solvent is used in the distillation which generates the reflux for the extraction, e.g., *extractive distillation* (extraction of aromatic compounds, see Section 5.2) or *azeotropic distillation* (extraction of acetic acid). In the extraction of metal salts (see Section 5.3) the purity is often achieved by adjusting the pH. Extraction is an isothermal process, normally carried out at ambient temperature and pressure.

Comparison with Absorption. In both absorption and extraction solvents are used which are recycled and thereby take up the required components selectively and then release them again. Selection of the most suitable solvents therefore plays an important role in the design of the two separation processes.

Applications of Liquid – Liquid Extraction. Liquid – liquid extraction is primarily applied where direct separation methods such as distillation and crystallization cannot be used or are too costly. Liquid – liquid extraction is also employed when the components to be separated are heat-sensitive (e.g., antibiotics) or relatively nonvolatile (e.g., mineral salts).

Liquid – liquid extraction is used in industry for the following purposes:

1) Separation of systems with similar boiling points (e.g., separation of aromatics from aliphatic hydrocarbons);
2) separation of highboilers and low concentrated solutes from aqueous solutions (e.g., phenol);
3) separation of mixtures with high boiling points (e.g., vitamins);
4) separation of temperature-sensitive compounds (e.g., acrylates, biotechnology);
5) separation of azeotropic mixtures (extraction of acetic or formic acid from aqueous media using, e.g., MTBE as solvent);
6) extraction of organic compounds from salt solutions (e.g., caprolactam);
7) extraction of salts from polymer solutions (e.g., ketone resins, polyols);
8) extraction of metal salts from low-grade ores (e.g., copper);
9) extraction of metal salts from wastewater (e.g., copper);
10) recovery of nuclear fuels (Purex process).

Figure 1. Principles of extraction – streams, phases and components

Processes applied in the petroleum industry, in metal-salt extraction and in chemical and biochemical processes are described in Chapter 5.

Only a general outline is given in this article. For further details, the reader is referred to books [1–7] and the Proceedings of the International Solvent Extraction Conference (ISEC) [8–17]. Data of liquid – liquid equilibria can be found in [18], [19] and [20].

Figure 2. Triangular diagram for representation of a three-component system

2. Thermodynamic Fundamentals

A comprehensive treatment of the thermodynamic fundamentals of phase equilibria is given elsewhere (→ Absorption; → Distillation and Rectification).

2.1. Graphic Representation of Phase Equilibria

2.1.1. Triangular Diagrams

Triangular diagrams (Fig. 2) are used for representing three-component systems. Every possible composition of the ternary mixture corresponds to a point in the diagram. Each corner of the triangle represents a pure component and its designation is marked at this corner. On the side opposite to this corner the mass fraction of this component is zero. The sides of the triangle represent the corresponding two-component systems. The proportions of the individual components in a mixture are obtained as follows: The mass fraction of each component is given by lines parallel to the side opposite to the corner which represents the pure component, from 0 kg/kg at this opposite side to 1 kg/kg at the corner. The numbering can be placed at the edges of the triangle, in which case it is advisable to extend the lines. The numbers can also be inserted in the middle of the lines. This makes the diagram easier to use but some of the numbers are always skew and inverted. The point P has the composition 0.5 kg/kg C, 0.2 kg/kg A, and 0.3 kg/kg B.

The following rules apply in the triangular diagram: If component C is added to a mixture of 0.8 kg/kg A and 0.2 kg/kg B, represented by the point D, then the composition of the new mixture follows the path of the straight line DC. On this straight line, and on all straight lines which pass through a corner, the ratio between the two other components which do not form the corner is constant.

If a mixture of composition U and one of composition V are combined then the resulting mixture lies on the straight connecting line UV. The composition of the final mixture is obtained by dividing the connecting line between the two original mixtures in inverse ratio to the quantities mixed (lever rule). The mixture M, for example, comprises three parts U and one part V, and the mixture G comprises three parts C and two parts D.

The concentration data obtained from the triangular diagram (e.g., point G: 0.6 kg/kg C, 0.08 kg/kg B, 0.32 kg/kg A; B : A = 1 : 4) apply to the total quantity of resulting mixture regardless of whether it is homogeneous or separated into several phases.

As every point in a triangular diagram corresponds to a composition there is no coordinate free for another reference variable. It is only possible to plot parameters such as lines of equal density, boiling points or other physical data, lines of equal activity coefficients or lines of phase boundaries.

Only ternary systems with miscibility gaps are suitable for extractions, and the boundary line between the liquid single-phase region(s) and the two-phase region is particularly important. This boundary line is called the *binodal curve* (Fig. 3). Every point on the binodal curve (except the plait point in systems with a complete binodal curve, see below) is in equilibrium with another binodal point. The lines which connect points in equilibrium with one another are called *tie lines.* All mixtures which correspond to a point on the tie line separate into two phases. The composition of these phases is given by the

Figure 3. Definitions of phase equilibria and mass fractions in a triangular diagram
A) Phase equilibria; B) Mass fractions

end points of the tie lines and their quantities are given by the lever rule. The equilibrium data have to be determined experimentally in each individual case. Lines parallel to the triangle sides CB and AC respectively, drawn through related points of equilibrium on both branches of the binodal curve, produce an auxiliary line, formed by the intersections of the parallels, and enable to construct any tie line as demonstrated in Figure 3 A.

Several types of triangular diagrams are shown in Figure 4. In every system with a complete binodal curve (*closed diagram,* Type II in Fig. 4) the end points of the tie lines draw closer and closer together until they finally coincide at the *plait point.* The plait point on the binodal curve represents a single phase which does not split into two phases.

Diagram I is called an *open diagram* in which B is not fully miscible with the substance to be dissolved. The capacity of such a solvent is correspondingly low and its selectivity is usually high (see Section 2.4).

In diagram II the substance to be extracted (C) is totally miscible with both A and B. This form of extraction diagram is often found in extractions where solute C and A are present in approximately the same quantities. If in this case the concentration of C in the AB-mixture is too high (higher than the concentration at the plait point) the system forms only one phase and extraction is not possible.

Diagram III shows a system where C has a miscibility gap with A. Its concentration in the B-rich phase is then substantially higher than in the feed. The diagram is typical for wastewater extractions.

Diagram IV is an open triangular diagram in which three liquid phases are formed in the middle concentration range. This behavior is often found in systems consisting of inorganic salts in aqueous solutions and organic solvents. The appearance of a third liquid phase can cause considerable difficulties during metal-salt extraction (see Section 5.3). The influence of pressure on the binodal curve and equilibria is negligible below values of several bar. The influence of

temperature is strong. The lower the temperature the more will the triangular diagram normally be filled by the miscibility gap.

Figure 4. Various types of phase equilibria in ternary systems
Type I: Open system, miscibility gap between the key component of the solvent (B) and solute C
Type II: Closed system, C is completely miscible with the key component of the feed (A) and the key component of the extraction solvent (B)
Type III: Open system, miscibility gap between A and C
Type IV: System with formation of three phases

2.1.2. Other Graphic Representations

Liquid two-phase systems comprising three components can also be plotted on rectangular coordinates. In many cases these diagrams are preferred because the measured values can be adjusted better and the configuration of the calculations is simpler. The most important forms of representation are shown for three mixtures in Figures 5, 6, 7. A comprehensive review of forms of representation is given in [27].

In the equilibrium diagram (Figs. 5, 6, 7 II) the mass fraction of C in the B-rich phase y_C (ordinate) is plotted as a function of this mass fraction in the A-rich phase x_C (abscissa). This diagram is analogous to the McCabe – Thiele diagram in distillation (→ Distillation and Rectification, Chap. 4.1.1.). It shows the relationship between equilibrium and operating conditions.

Figure 5. Representation of phase relationship of the ternary system heptane (A), diethylene glycol (B), benzene (C), at 20 °C. All data refers to mass fractions.
I) Triangular diagram; II) Equilibrium diagram; III) Distribution diagram; IV) Selectivity diagram

Figure 6. Representation of phase relationship of the ternary system trichloroethylene (A), water (B), caprolactam (C), at 20 °C. All data refers to mass fractions.
I) Triangular diagram; II) Equilibrium diagram; III) Distribution diagram; IV) Selectivity diagram

In the example shown in Figures 5, 6, 7 III the distribution ratios of the extracted components (benzene, caprolactam or phenol) are plotted as functions of their mass fractions in the A-rich phase (curve a) and in the B-rich phase (curve b). The distribution ratio k indicates how much better or worse the extracted component is soluble in the B-rich than in the A-rich phase; the minimal solvent ratio can be evaluated directly from Figures 5, 6, 7 III. The distribution ratio therefore is an important criterion for the selection of a solvent. The mass fraction in the A-rich phase is easier to visualize as a reference variable. At the feed stage it corresponds approximately to the initial feed concentration. It governs the yield at the raffinate outlet. On the other hand, showing k as a function of y_C (curve b) has the advantage that it permits comparisons with respect to solvent loading. It is always advisable to plot both curves because their suitability for extrapolation and interpolation varies considerably in the different concentration ranges.

In the selectivity diagram (Figs. 5, 6, 7 IV) the quotient of two distribution ratios is plotted as a function of the mass fractions of component C in the A-rich (curve a) and in the B-rich phase (curve b). The quotient of the distribution ratios for the extracted component C (y_C/x_C) and for A (y_A/x_A) corresponds to the relative volatility in distillation (see Section 5.1). It is a measure of the selectivity of a solvent.

2.2. Measuring Methods of Phase Equilibria

Whenever possible a ternary system is used as the starting point for measurement of liquid – liquid equilibria. It is first necessary to establish which of the three possible binary systems have a miscibility gap and which are completely miscible. For this purpose it is sufficient in each case to mix the two substances in ratios of 3 : 1, 1 : 1 and 1 : 3. If no formation of two liquid phases occurs in any of the cases then the system is fully miscible and not suitable for extraction.

Figure 7. Representation of phase relationship of the ternary system water (A), butyl acetate (B), phenol (C), at 20 °C. All data refers to mass fractions.
I) Triangular diagram; II) Equilibrium diagram; III) Distribution diagram; IV) Selectivity diagram

If, for example, A and B are not miscible while the third, C, is completely miscible with the two others (closed triangular diagram) then the binodal curve can be determined as follows. Equal amounts of A and B are placed in a controlled-temperature vessel which can be shaken (e.g., an Erlenmeyer flask in a thermostat) and substance C is added until the mixture becomes clear. In two further experiments pure A or B is placed in the vessel and in each case the second substance is then added until turbidity occurs. Three points have now been obtained in the triangular diagram and the approximate shape of the binodal curve is known.

For precise determination of the binodal curve, mixtures of A and C containing 0.9, 0.8, 0.7 (etc., for as far as appears necessary) kg/kg A are prepared and titrated with B at constant temperature. When turbidity is reached titration is ceased and a small quantity of the original AC mixture is added until the solution is clear again. Then a characteristic variable such as refractive index, density, dielectric constant, freezing point, boiling point, etc. of this mixture can be determined. In the same way mixtures of C and B are titrated with A. This measurement gives the precise shape of the binodal curve and all the compositions lying on this curve can be defined by a physical parameter.

To determine phase equilibrium and therewith the tie lines, i.e., the points which are in equilibrium with one another, a mixture from the two-phase region is placed in a controlled-temperature, shaking cylinder. Equilibrium is established by shaking. The phases are allowed to settle and are separated by draining off into different vessels. Then their quantities are determined and the physical variable measured during determination of the binodal curve is then measured for both phases. This immediately gives the two tie line points. Furthermore, both phases can also be analyzed by well known chemical methods, such as gas or liquid chromatography and titration. The correctness of the measurement can be checked by connecting the two tie line points in the triangular diagram. The connecting line must pass through the point of the original mixture, and this point must divide the length of the tie line in inverse ratio to the quantities of the two phases.

If a system of more than three components has to be measured then several components are combined into one group in order to arrive at a ternary system again. Determination of a binodal curve would still be possible in such a case but the two phases into which the test mixture separates are no longer identical with the mixtures which were obtained during the determination of the binodal curve. It is therefore better to allow the mixture to reach equilibrium conditions in a controlled-temperature, shaking cylinder, separate it and then analyze the phases using some preplanned method.

The time consuming step in the determination of equilibria is the preparation of the experiment, such as purification of the substances, setting up the calibration curves, etc. Therefore it is senseless to restrict the number of measured points and use interpolation methods. To increase the accuracy a material balance is set up for each component and the measured points are adjusted by drawing the curves from Figures 5, 6, 7.

2.3. Empirical Correlations of Phase Equilibria

In ternary systems, the use of empirical correlations to represent the binodal curves and distribution equilibria of component C is of advantage [28]. The mutual solubilities of the liquid phases are usually determined by a laboratory turbidity titration. The binodal curve is then determined by extrapolating the measured values (see Section 2.2). In Type I systems with an open miscibility gap, the binodal curve can be simply described by parabolic equations:

$$x = D' + E' x'_{\mathrm{A}} + F' x'^2_{\mathrm{A}}$$

$$y = D'' + E'' x''_{\mathrm{B}} + F'' x''^2_{\mathrm{B}}$$

where x'_{A} is the mass fraction of A in the A-rich phase, x''_{B} the mass fraction of B in the B-rich phase and D', D'', E', E'', F' and F'' are coefficients.

In systems with a closed miscibility gap (Type II), the parabolic equations are only valid for the lower parts of the curve; they cannot be used to represent the entire binodal curve. The best equation for the closed binodal curve is that proposed by Hlavaty [29]. The correlation is derived from a polynomial equation and has the advantage that the binodal curve ends exactly at the binary solubility points. Its disadvantage is, however, that the lower, in practice virtually linear, regions of the binodal curves are represented in wave form as a result of the polynomial equation. The Hlavaty equation should, therefore, be used with caution.

The equilibrium distribution of solute C in the A- and B-rich phases is generally determined independently from the binodal curve by means of laboratory experiments. The mass fraction x_{C} and y_{C} of the two phases in thermodynamic equilibrium are thus obtained and determine the positions of the end points of the tie lines on the binodal curves (see Section 2.2). Equations for correlating and interpolating the end point of the tie lines are described in the literature, they are primarily exponential equations such as those proposed by Othmer and Tobias, and Hand [1]. However, all exponential equations generally fail when the concentration of C is very low. To allow a more accurate estimation of distribution equilibria and extraction processes at the low raffinate concentrations that are of industrial importance, Bender and Block [28] proposed the following correlation for the distribution ratio K:

$$K = G_1 + G_2 x'_{\mathrm{C}} + G_3 x'^2_{\mathrm{C}} + G_4 x'^3_{\mathrm{C}}$$

The coefficients G_i must be fitted to the measured values of the tie lines x and y. Although the equation does not generally permit extrapolation of the curve above the measured values to the plait point, the distribution coefficient K can be obtained accurately up to x and $y \to 0$.

The empirical correlations are simple and clear. They can be calculated quickly with appropriate computer programs and give an accurate representation of the measured liquid – liquid equilibria. However, these advantages are accompanied by several disadvantages. The correlations can only be used with ternary systems and do not allow extrapolation to higher multicomponent systems. Extensive laboratory work is required to determine the mutual solubilities of components A and B as a function of the concentration of C as well as the equilibrium distribution of component C. Systematic measurement errors cannot be detected because the experimental values are empirically correlated.

2.4. Selection of Solvent

The selection of the most suitable solvent is one of the hardest problems of the extraction, and the decision made has a great influence on the economy of the process. The solvent must fulfill two basic requirements:

1) it must have a miscibility gap with the A-rich phase, and
2) it must be a better solvent for component C than for A.

A great number of methods have been recommended for discovering suitable solvents [30], [31]. The more empirical strategy of former times is being replaced more and more by a systematic research with the aid of data banks [26]. The concept of polarity is used for characterizing suitable parameters [32].

The greater the difference in polarity between two liquids, the greater is the probability that they have a miscibility gap. The substance to be extracted will have a higher concentration in the liquid to which it is closer in polarity.

However, the relationships are not so simple that only a scale of polarities has to be set up and the difference in polarity at which miscibility gaps occur read off the scale. For example, aniline, phenol, and furfural have miscibility gaps with both water and hexane. Acetone, ethanol, and dioxan which have a similar polarity are miscible with both water and hexane. The molecular form and the size of the molecule also contribute to solvent behavior. The behavior of solvents towards hydrocarbons has been investigated particularly intensively [33], [34]. It is also possible to obtain effects from mixing two solvents which could not be predicted from the properties of the mix components [35], [36].

The most important property of a solvent is its *selectivity.* This indicates how much better the solute is dissolved than the A-rich phase. As can be seen from Figures 5, 6, 7 III the selectivity is strongly dependent on concentration.

In addition to selectivity the *capacity* of a solvent is also important. This is defined by the distribution coefficient of C between the B-rich and A-rich phases and determines the quantity of solvent which has to be recycled. When testing different solvents for a specific extraction task it is often found that solvents with higher selectivities have lower capacities and vice versa. The greater the throughput of a plant the more important the capacity of the solvent is for the economy of the process. If there are several possible solvents for a process then their behavior with respect to selectivity and capacity can be tested with a gas chromatograph without starting with time-consuming equilibrium measurements [37].

In addition to these basic requirements there are also other criteria which must be taken into consideration when selecting a solvent and which sharply reduce the number of possible compounds. Most important is the availability of the solvent in commercial quantities at an economically acceptable price. It is then necessary to find data concerning boiling points, density, viscosity and – where available – information about solubility [38], [39].

The *boiling point* of the solvent is important because the extracted component is usually separated from the solvent by distillation and the boiling point difference determines the reflux ratio in this distillation. If the solvent boils at a higher temperature than the solute, this solute is distilled overhead. If it is necessary to recycle a great deal of solvent then the solvent has to be purified by distillation in a subsequent step; the specific heat which is required for heating the solvent to its boiling temperature must also be taken into account. Too great a temperature difference is then a disadvantage.

The *density* of the solvent is important for obtaining a sufficiently large difference in densities between the two liquid phases for the separation process. Chlorinated compounds are suitable if a solvent with a high density is to be used, and particularly low-density compounds are found among the saturated hydrocarbons and ethers.

The *thermal stability* of the solvent can be highly significant. The researcher hardly ever finds the answer to this question in the literature and is directed to carry out his own measurement. It is necessary to know (1) how much solvent make-up will be needed in the process; (2) whether a regeneration process for continuous removal of decomposition products needs to be installed. Very careful tests must be carried out to find out whether decomposition products can contaminate the extract or have a corrosive effect on the construction materials of the plant. Sometimes the toxicological properties and biological

degradation of a solvent have to be considered [40].

The *viscosity* should be as low as possible as this favors mass transfer and phase separation. However, this property is less significant than those mentioned above. If the possible solvents have been reduced to a manageable number after testing all the aspects then the individual properties can be evaluated with a point system to discover the best solvent.

The *surface tension* is another important parameter because it influences the energy demand necessary to produce a suitable drop dispersion. High surface tension gives rise to formation of stable drops and needs a high energy input. A solvent with a high surface tension decreases the danger of producing an emulsion. The surface tension is dependent on the concentration of the transfer component. Further properties such as suitability for regeneration, disposability, costs, combustibility, toxicity and corrosiveness also have to be taken into account to select a suitable solvent.

Bound up with solvent selection is the choice of the dispersed and the continuous phase, respectively. Direction of mass transfer and phase ratio have to be taken into account. The direction of mass transfer influences the surface tension and in this way can promote or hamper the coalescence of drops. The phase to be dispersed should be the one which impedes the drop coalescence to produce stable drops, and the one with the higher flow rate to obtain a mass transfer area as large as possible.

2.5. Calculation of Theoretical Stages

(→ Absorption, Chap. 4.; → Distillation and Rectification, Chap. 4.)

Two possibilities exist to calculate the mass transfer performance of extractors. The first one uses the concept of theoretical stages and is based on the assumption that concentration equilibrium is established in every section of an extractor. This assumption can be fulfilled only in the mixer – settler with long contact times of the phases involved. In this concept the total height of an extraction column is given by the product of the number of theoretical stages (NTS) and the height equivalent of a theoretical stage (HETS). NTS follows from a material balance in combination with the distribution equilibrium; HETS depends on fluid dynamics and mass transfer in the columns and comprises all real conditions as for instance the conditions of phase mixing. Therefore this concept is preferred only for rough estimations in practice because it is easy to handle and sufficient for preparation of laboratory experiments. In the following sections, the method will be presented by aid of equilibrium diagrams.

The second possibility is a stream concept. The column height required for a given throughput and concentration gradient of phases along the column can be calculated from height integration of a set of differential equations, derived from a differential material balance and the local mass transfer between the both phases. The stream concept supplies the course of concentrations along the column and is suitable for analysis of the dynamic behavior of a column and for taking into account the drop population inside the column. It is preferred until now for scientific investigations, e.g., for stationarily operated pulsed sieve tray columns [45], [47–49], [51], [62] and for instationarily operated rotating extractors [65], [68].

2.5.1. Selection of Calculation Methods

The conditions for an applicable method of calculation are set by the problem to be solved, by whether simplified assumptions are permissible and by the main influencing variables of an extraction problem. They are, therefore, different. The following points should be considered when selecting a method of calculation:

1) Do changes in mass flows have to be considered?
2) Is the distribution ratio constant?
3) Is the concentration gradient large or small?
4) Does only one component have to be extracted, or are there several with different distribution coefficients?

2.5.2. Specific Methods

Method 1. If the following conditions are satisfied:

1) the component A and solvent B are virtually insoluble in each other,

Figure 8. A) Material balance of a column cross section; B) Corresponding operating diagram

2) the changes in mass flow rates of the extract and raffinate phase are negligible (e.g., for a low content of C in the feed)

then the compositions of the phases can be expressed as loads. If a material balance is made as shown in Figure 8, the two loads Y_c and X_c in a given column cross section can be related as follows

$$Y_C - Y_{C,S} = \frac{\dot{m}_F}{\dot{m}_s} \cdot (X_C - X_{C,R})$$

When plotted on the equilibrium diagram, this relation gives a straight line, the balance or operating line. The number of theoretical stages required to obtain a desired decrease in the concentration of C from $X_{C,F}$ to $X_{C,R}$ can be determined graphically by constructing a series of steps as shown in Figure 9. The result of the use of the steps often means that the load obtained from C in the raffinate ($X_{C,R}$) does not correspond to the required load ($X_{CR,req}$).

Figure 8 also shows the position of the balance line for the minimum extractant ratio V_{min}

$$V_{min} = \dot{m}_{s,min} / \dot{m}_F$$

The desired enrichment of the feed with C using the minimum amount of extractant $\dot{m}_{s,min}$ can only be achieved with an infinite number of stages.

Figure 9. Construction of steps in the operating diagram to obtain the number of theoretical stages (NTS)

Method 2. Figure 10 shows the equilibrium diagram for the system toluene – ethylene glycol – water as a double logarithmic plot. This type of plot is useful if the distribution ratio varies considerably, despite low loading, and the concentration range considerably exceeds the desired raffinate purity. In this case the operating line is at an angle of 45°.

$$\log(Y_C - Y_{C,S}) = \log\left(\frac{\dot{m}_F}{\dot{m}_S}\right) + \log(X_C - X_{C,R})$$

Figure 10. Determination of the number of stages for a variable distribution ratio and a high degree of depletion

The position of the straight lines is determined by the extractant ratio V. The number of required theoretical stages can be determined by constructing a series of steps.

Method 3. If the distribution ratio K is a constant, further simplification is possible; in analogy with the Colburn equation (→ Absorption, Chap. 4.2.), the number of theoretical stages NTS can be calculated:

$$\mathrm{NTS} = \frac{\log\left[1+(E-1)\left(\frac{X_{\mathrm{C,F}}}{X_{\mathrm{C,R}}}+\frac{Y_{\mathrm{C,S}}}{X_{\mathrm{C,R}}}\right)\right]}{\log E} - 1$$

where the extraction factor E is given by

$$E = K \cdot \dot{m}_{\mathrm{s}}/\dot{m}_{\mathrm{F}}$$

If NTS is known and the degree of depletion $X_{\mathrm{C,R}}/X_{\mathrm{C,F}}$ is desired, the following equation is obtained:

$$\frac{X_{\mathrm{C,R}}}{X_{\mathrm{C,F}}} = \frac{(E-1)\left(1+\frac{Y_{\mathrm{C,S}}}{X_{\mathrm{C,F}}}\right)}{E^{(\mathrm{NTS}+1)}-1}$$

This equation can only be solved iteratively; a graphical solution is shown in Figure 11.

Method 4. If none of the above-mentioned conditions is satisfied, and the extraction problem can be limited to consideration of the three key components, the calculation can be carried out with the aid of the triangular mass fraction diagram. This method is based on the mixing rules described in Section 2.1.1.

The specified compositions of the feed F and solvent S streams are plotted on the phase equilibrium diagram for the ternary mixture (Fig. 12). For material balance of the feed and product streams, the column can be assumed to be a simple mixing vessel. The composition M of the mixture lies on the tie line FS; the position of M on the tie line is determined by the ratio $\dot{m}_{\mathrm{S}} : \dot{m}_{\mathrm{F}} = \mathrm{MF} : \mathrm{MS}$. The compositions of the raffinate R and extract E streams leaving the column are obtained from the intercepts of the tie line with the binodal curve. The raffinate composition is determined by the desired mass fraction of C in the raffinate ($x_{\mathrm{C,R}}$). The composition of the extract E is given by the point at which the extended line RM intersects the binodal curve. The ratio $\dot{m}_{\mathrm{R}} : \dot{m}_{\mathrm{E}}$ is obtained by applying the lever rule. The quantities and the compositions of the incoming and outflowing streams are thus determined.

The required number of stages in a countercurrent column are obtained by using the *pole point procedure.* The procedure can be explained by imaging a stream P to maintain the material balance. Mixing of this stream with the raffinate stream R gives the composition of the solvent stream S. To maintain the material balance the extract on the other hand must be composed of the feed stream F and the imaginary stream P. The imaginary stream P can thus be regarded as a common mixing partner for F and R to maintain the compositions of E and S. The composition of the imaginary stream P is represented by a point outside the triangular diagram, the pole point. The imaginary mass fractions of the three components in the pole point can be > 1 or negativ. If the material balance boundaries for the individual stages are taken as shown in Figure 13, the above procedure gives the stage extracts E_2, E_3, etc. from the mixture of the imaginary stream P and the individual stage raffinates in the proceeding stages R_1, R_2, etc. The composition of the raffinates R_1, R_2, etc. are linked to the corresponding extracts E_1, E_2, etc. via the distribution ratios (tie lines).

2.5.3. Evaluation of Stage-Number Calculation for Process Design

In order to determine the operating conditions and the dimensions of the equipment used for

Figure 11. Dependence of the theoretical number of stages, the degree of depletion, and the yield on the extraction factor *E*

Figure 12. Pole point construction – balance diagram

Figure 13. Pole point construction – operating diagram

extraction, the results of several stage-number calculations must be plotted in a diagram showing the relationship between the solvent circulation, the number of stages, and the residual content of solute in the raffinate. Such a diagram is shown in Figure 14 for mixture II (see also Fig. 6). It represents the extraction of a 10 % solution of caprolactam in trichloroethylene with water as the extraction solvent. The favorable operating region is usually located in the region which shows the most pronounced curvature. Other variables (e.g., the effect of temperature and the residual loading of the solvent with solute) may have to be taken into consideration.

3. Apparatus

3.1. Survey

Extraction apparatus can be classified into countercurrent columns, centrifugal extractors, and mixer – settlers. All industrial equipment designs use the principle to disperse one of the two liquids into the other in order to enlarge the contact area for mass transfer and to influence the drop generation by energy input such as mixing or pulsing. After the resulting droplets have been contacted with the continuous phase long enough to allow the extractable component(s) to migrate to the dispersed phase, both liquids have to be separated again. Densities will define the flow directions of the phases: The heavier liquid flows from top to bottom, the lighter one from bottom to top. Accordingly, the fluids have to be transported to the apparatus and removed by pumps.

In the following chapter, a few typical designs have been selected from the large number of equipment designs actually used in industry. A more detailed treatment can be found in literature, especially in [5] and [6].

3.1.1. Columns without Energy Input

The simplest extractor is the *spray column* (Fig. 15 A). The spray column achieves only very small numbers of separation stages and is rarely used nowadays. If the column of Figure 15 A is filled mainly with the heavier liquid, the lighter liquid breaks at the feeding point into drops that rise in the continuous liquid. Drops reaching the interface are kept at this position by controlling the bottom discharge (LIC). There, they will then gradually coalesce and form a continuous layer floating on top of the continuous liquid.

The reverse procedure is possible as well, as shown in Figure 15 B. Here, the distributor is located at the top and the water interface, called the principle interface, is controlled at the bottom of the column by filling it mainly with the lighter liquid. In this case, the heavier liquid is the dispersed one, broken into droplets descending in the lighter liquid. The principle interface can be adjusted at any height (between top and

Figure 14. Extraction of caprolactam from a 10 wt % solution in trichloroethylene with water as solvent

Figure 15. Columns without energy input (LIC = level indicating controller)
A) Spray column (light phase dispersed); B) Packed column (heavy phase dispersed); C) Sieve plate column (light phase dispersed)

bottom) of the column as needed, thus the heavier liquid being dispersed above and the lighter liquid below the principle interface.

Countercurrent columns are equipped with settling zones at the top and the bottom, with coalescing aids provided if necessary. The liquids should never be fed into the column in these settling zones because this would cause hydrodynamic instability of the column thus reducing the operational performance. The dispersed liquid often cannot be selected from theoretical considerations, but only by aid of experiments in a pilot column using the real material system.

Packed columns (structured and unstructured) and *sieve plate columns* have been adopted from distillation technology (→ Distillation and Rectification, Chap. 8.). In *packed columns* drop formation occurs on entry of the dispersed phase in the packed bed (Fig. 15 B). The drops rise through the packed bed without significant further dispersion. However, mass transfer takes place mainly during the formation of a new interfacial area. This explains the low efficiency of packed columns [6, Chap. 8].

In a *sieve plate column* with downcomers, as shown in Figure 15 C, the lighter dispersed phase coalesces beneath each plate to give a continuous layer. Its buoyancy presses the liquid through the holes of the sieve plates, producing jets which disintegrate into drops. The continuous liquid flows through the downcomers from stage to stage and then across the plates. In the case of low interfacial tension the layers of coalesced phase are too small for a symmetrical operation of the plates. Then it is advantageous to use dual flow plates without downcomers [57].

Sieve plate columns have the advantage over packed columns that new drops are formed at each tray. However, the drop load of the plate is often irregularly distributed, especially if the column diameter is large (more than 1 m). This is the reason why sieve plate columns can reach efficiencies of 10 – 15 % only in rare favored cases. Moreover, since columns are generally built with a plate spacing of 0.3 m, even simple separations require considerable overall heights.

Mass transfer between the two liquids can be substantially improved by application of additional mechanical energy in form of superimposed agitation or pulsation, resulting in higher turbulence near the drops and enlarged mass transfer area due to smaller drop sizes.

3.1.2. Pulsed Columns

The simplest design of pulsed column is the *pulsed sieve plate column* (Fig. 16 A). A piston pump with an electrical or an air-pressure drive causes the entire liquid content of the column to vibrate. Both phases are alternately forced through the holes in the rhythm of the pulsation. The downcomers used in the conventional sieve plate column are thus superfluous. The dispersed phase does not coalesce above or below the plates to give a continuous layer. The pulsation shock flings the drops off the plate faster than would be possible as a result of only the density difference. This leads to a fine, uniform drop distribution and hence enlarges the mass transfer area. Applications are limited by the physical properties of the substances concerned and high throughputs. Systems which emulsify easily cannot be processed in pulsed columns just as sticky and greasy liquids. For very large throughputs (column diameter > 0.6 m), the pulsed volume and pulsing power become very high; however, pulsing units for large column diameters have been developed.

The separation effect of the column decreases with increasing diameter, this has not yet been fully investigated. The plate spacing is 50 – 100 mm. Larger plate spacings favor backmixing and hence reduce the efficiency of the column. Smaller plate spacings lead to a strong decrease of the throughput. Sieve plates have cylindrical holes and a triangular pitch. The relationship between the fractional free area φ, the hole diameter d_i and the pitch p is given by

$$\varphi = \pi d_i^2 / \sqrt{12p^2}$$

For usual liquid – liquid systems sieve plates with hole diameters from 2 to 4 mm resulting in free areas of 23 to 40 % are recommended [6, Chap. 10], the lower value of 23 % is used for high and the higher value of 40 % for low interfacial tensions. Free areas less than 20 % are used for liquids with higher viscosities [58].

The plate material has a pronounced influence on drop formation and hence on the separation efficiency. The plate material and phase selection must be matched in such a way that the

Figure 16. Pulsed and reciprocating-plate columns (Light phase dispersed)
A) Pulsed sieve-plate column; B) Reciprocating-plate column (Karr)

plates are wetted by the continuous phase but not by the dispersed phase, because this would lead to strong coalescence effects. If, for example, an aqueous phase is to be dispersed into drops, metal trays are unsuitable, but plastic plates are satisfactory. The sharp edged side of the sieve plate, which is due to manufacturing, should exactly face the flow direction of the dispersed liquid so that drops will shear at the edges of the holes. Gaps between the sieve plate edge and the column wall should be avoided by precise construction or by applying edge-sealing elements made of materials which are wetted by the continuous liquid.

In most cases, piston pumps or diaphragm pumps are used as the pulsators. The pulsing frequencies are between 30 and 150 min^{-1}, with pulsing amplitudes from 5 – 15 mm (relative to the column cross section). (Pulsing amplitude is defined as the distance between upper and lower center of the pulsing motion in the active part of the column.) The dispersed phase has to be fed into the column via a distributor. The mean drop diameter of the predispersed swarm should be larger than the mean drop size in the active part of the column, otherwise the hydrodynamics of the column would mainly be affected by the distributor. The holes in the distributor should be very sharp-edged to avoid very fine drops. Even in packed columns, the separation effect can be substantially improved by pulsing of the continuous phase, at the expense of a reduced throughput. The increased performance results from greater shear forces causing a reduction in drop size and an increase in interfacial area [6, Chap. 8]. As in distillation columns, the phenomenon of maldistribution in randomly packed columns of larger diameter can be overcome by use of structured packings. These packings lead to a good cross-sectional mixing and have a higher capacity, typically a total flow rate of both phases of approximately 100 $m^3m^{-2}h^{-1}$ compared to 30 $m^3m^{-2}h^{-1}$ for a randomly packed column. Structured packings are particularly suitable for low interfacial tension systems or for small density differences; separation efficiency is nearly independent of scale-up. Hydrodynamics and mass transfer performance are well investigated [6, Chap. 8], [59].

Pulsing Units. The use of pulsed columns is currently limited to small and medium throughputs. The column diameter is limited by the pulsing unit. For very large throughputs, the pulsed volume becomes so large that the use of a piston pump as the pulsing unit causes difficulties. Consequently, pulsing units have been developed which operate without a piston pump. The pulsator developed by Misek (Fig. 17) is based on

a centrifugal pump. The pump (e) is connected on both the suction side and the delivery side to pressure vessels which are alternately connected to the column by means of a rotating valve (c). With the valve setting shown in Figure 17 A, the pump delivers the liquid into the column via the discharge drum (b), taking the rate delivered from the suction drum (a). After changeover of the valve (Fig. 17 B), the pump delivers from the column via vessel (a) into drum (b). The pump thus always delivers continuously in one direction. Reversal of the direction of flow in the pulse line is effected by the change-over valve (c) in accordance with the pulse frequency. A pulsator based on this principle has been developed by Bronswerk/DSM (Fig. 17 C), and is now in operation for columns with a maximum diameter of 2.7 m.

For large pulsed volumes, the hydraulic pulsator from Wepuko [60] is also suitable (Fig. 18). It is flanged directly to the lower bottom of the column end and acts in the direction of the column axis. The pulsing piston is connected via a common piston rod to a working piston, the hydraulic drive of the piston is a rapidly reversible radial piston pump.

Reciprocating-Plate Columns. In another approach for solving the problem of large throughputs, the plates, and not the liquid, are made to reciprocate, so that the pulsing pump is eliminated. This principle led to the development of the reciprocating-plate column which can be regarded as the converse of the pulsed sieve plate column. In the pulsed sieve plate column, the trays are fixed and the entire liquid content of the column is caused to vibrate; in the reciprocating-plate column, the plates are moved. In both cases, the liquid undergoes an oscillating motion relative to the plate.

In the *Karr column* (Fig. 16 B), sieve plates with a free area of about 60 %, a 10 – 15 mm hole diameter, and a 25 –50 mm plate spacing, are mounted on a central shaft. The complete pack is moved up and down, driven by an eccenter.

Figure 17. Pulsator with rotating valve

a) Suction drum; b) Discharge drum; c) Rotating valve; d) Column; e) Centrifugal pump

The relatively large free area of reciprocating plate columns allows much greater throughputs than conventional pulsed columns. However, recent investigations showed that pulsed sieve plate columns can be equipped with larger free areas, too. Both types of pulsed columns show very similar performances and operational behavior if they are equipped with the same free areas [61]. Research on the established types of pulsed columns has been very intensive since the 1970s.

Figure 19. Rotating disk contactor (RDC)
a) Rotating disk; b) Stator ring

3.1.3. Columns with Rotating Internals

Rotating Disk Contactor (RDC). In the RDC (Fig. 19 A), stator rings are mounted at close intervals. Disks are fitted between the rings to a rotating shaft. The rotating disks fling the drops of the dispersed phase off centrifugally, onto the stator rings where they are braked and deflected. The drop distribution is excellent and can reach the emulsification limit as the rotational speed increases.

The RDC has a relatively simple construction with a large free cross-sectional area. On the one hand, it reaches large throughputs, on the other hand it favors backmixing of phases causing a decrease of efficiency. A large range of throughputs is possible without remarkable decrease of efficiency. The loading limit is generally lower than in pulsed columns. The RDC is unsuitable for mixtures which tend to form emulsions and for products containing dirt. The separation efficiency decreases sharply with increasing diameter. Nevertheless, successful RDCs of up to 3500 mm in diameter have been constructed. They are thus suitable for greater throughputs than pulsed columns and are preferably used to operate with large product flows when the demands on separation performance are only low as for instance in the oil industry or in wastewater treatment [42].

As in pulsed columns, the wetting behavior also influences drop formation in the RDC, and should therefore be taken into account when selecting a material for the column internals.

Kühni Extractor. The Kühni extractor (Fig. 20 A) uses a turbine as the mixing element. Perforated partition disks separate the extraction stages and reduce backmixing.

This apparatus is also used for performing reactions between two liquid phases; the residence time can be adjusted via the free area of the perforated disk.

QVF-Extractor. The QVF extractor RZE (Fig. 20 B) uses blade stirrer as mixing elements. The partition disks have meander-formed metal stripes at the inner circumference to reduce the phase dispersion by channeling of both phases. The operational behavior is similar to that of the Kühni extractor (see Fig. 20 A).

Figure 20. Columns with rotating internals
A) Kühni extractor; B) QVF extractor

Graesser Contactor. The Graesser contactor (Fig. 21) is another type of rotating equipment. Here, not only the internals but the entire apparatus rotate. Internal half-tubes are fitted as scooping elements in a horizontal rotating cylinder. Due to the rotation, the half-tubes transport part of the heavy phase into the overlying light phase, and vice versa. To reduce backmixing, the extractor length is divided into chambers by partition disks. Because of its low dispersing effect, this equipment is particularly suitable for systems which tend to emulsify. The throughput is low compared with other extractors.

Figure 21. Graesser contactor

3.1.4. Mixer – Settlers

Mixer – settlers consist of single or several stages in series (Fig. 22 A), each stage consisting of a stirred vessel and a settling vessel (Fig. 22 B). Various arrangements are possible such as cocurrent, countercurrent, or crosswise flow of phases. The mixer – settler is the only extractor that reaches stage efficiencies of nearly 100 % and is almost insensitive for load fluctuations.

This extractor has the advantage that backmixing can be completely precluded due to the complete phase separation in each stage. As a result, there are no transfer problems in scale-up. The favorable efficiency is almost completely retained even for large throughputs. Any number of separation stages can be built, and, moreover, throughput does not appear to be limited. These advantages account for the widespread use of mixer – settlers in industrial processes for many decades. However, early mixer – settler equipment was very complex. Each separation stage consisted of a stirred vessel and a settling vessel. The two phases had to be pumped between the individual stages. Each settler needed an interface level control. The horizontal arrangement resulted in a large area requirement.

In an effort to overcome these disadvantages of the mixer – settler batteries without foregoing any of their advantages, a number of different designs were developed. Mixer – settlers are used

Figure 22. Principle of a mixer – settler
A) Flow Sheet; B) Arrangement

in two different areas. Industrial-scale equipment is used to obtain extremely high throughputs when a small number of stages is needed, e.g., in the extraction of metal salts. Laboratory-scale devices are employed in process development to check the number of calculated stages as a function of the ratio solvent.

Large-scale mixer – settlers were originally developed to extract copper from dilute aqueous solutions. The basic design is a *box-type mixer – settler* according to Denver (Fig. 23). The mixing and separating zones are combined in a single unit and are separated by an overflow weir for the light phase and an underflow slit for the heavy phase. The individual stages are arranged so that the outlet of the settler also acts as the inlet of the mixer. The agitator has two functions, it disperses and conveys the liquid phases. These functions may conflict with one another. The rate of rotation necessary to overcome the conveying height may be too high when unstable systems must be dispersed, causing problems in phase separation, e.g., a high degree of entrainment. Mixing pumps with low shearing forces, and thus a low mixing intensity, have been developed to avoid these difficulties. Examples are the Pumpmix impeller used with the *Davy McKee mixer – settler* (Fig. 24 A) and the *IMI turbine pump-mix unit* (Fig. 24 B).

Figure 23. Box-type mixer – settler (Denver)
A) Side view; B) Ground plain

A further development of the Davy McKee mixer – settler has been described [43]. Each stage consists solely of a vessel in which mixing and separation occur. The product inlet and the agitator are located in the middle and create a dispersion zone. The light phase separates out at the top and the heavy phase at the bottom.

In the *Lurgi tower extractor,* the battery of adjacent settlers is replaced by a space-saving

Figure 24. Industrial mixer – settlers
A) Davy McKee mixer – settler; B) IMI turbine pump-mix unit (cross section A – B – C – D shown in the lower part); C) Lurgi tower extractor

tower design in which the settlers are arranged on top of each other. External centrifugal pumps are used for mixing (Fig. 24 C). Like all mixer – settlers, this device is suitable for very large throughputs provided that the liquid system can withstand the high energy input of the mixing pump. Backmixing to a certain degree is unavoidable since the stages have hydrodynamic connections.

Multistage mixer – settlers are a valuable aid in process development on a laboratory scale. They can be integrated in "mini plants"; at this stage of development no decision should be made which type of equipment is suitable for the large-scale plant. Several examples of laboratory mixer – settlers are shown in Figure 25.

3.1.5. Centrifugal Extractors

Centrifugal extractors are used when the density difference between the two phases is insufficient to produce a countercurrent under gravity. The best known of these devices is the *Podbielniak centrifugal extractor* (Fig. 26 A), in which cylindrical perforated sheets are concentrically arranged as a compact rotor on a high-speed shaft. The heavy phase is fed in via the shaft and moves outwards due to the centrifugal force. The light phase moves in the opposite direction. Similar to columns, either the light phase or the heavy phase can be dispersed into drops, as desired. If the light phase is to be dispersed, the main interface must be located near the shaft. Depending on the system the number of stages which can be combined in one unit is limited to 3 to 4 theoretical stages.

The *Robatel centrifugal extractor* is based on a totally different principle and allows greater numbers of stages (Fig. 26 B). Disks serving as the mixing element are centered on a vertical stator. The housing is divided by annular disks into a number of stages and rotates around the central shaft. Each stage consists of a mixing chamber and a settling chamber. The disks each dip into the mixing chamber. An extensive review on operation and calculation of centrifugal extractors is given in [6, Chap. 14].

Centrifuges are more complex than columns, their investment and maintenance costs are correspondingly high. They can therefore only stand comparison with columns in cases where

Figure 25. Laboratory mixer – settlers
A) Normag mixer – settler; B) Schott/QVF mixer – settler

they have advantages which no column can provide. Phase separation is possible even in systems having a density difference as low as 15 kg/m^3. Systems with large differences in viscosity can be processed, since the high shear forces effect intensive mixing.

As a result of its compact design, the centrifugal extractor is a space-saving apparatus with an extremely small operating volume and a short residence time. These advantages can be desirable if expensive solvents or substances of limited stability are used. The steady state is reached soon after starting. This extractor is therefore suitable for batchwise operation and frequent changes of products. Extraction under pressures of up to 5 MPa is possible.

3.2. Fluid-Dynamic Fundamentals

A comprehensive treatment of fluid-dynamic fundamentals is given elsewhere (→ Fluid Mechanics).

3.2.1. Problems and Process Strategy

In Section 2.5, it was shown how the number of theoretical stages and the flow diagram of the unit operation "extraction" are calculated on the basis of equilibria. The selection and design of apparatus are based on fluid dynamics and are not carried out until the thermodynamic design is completed. At present, model experiments are still necessary for the design of extraction apparatus. For this reason, a knowledge of the operating characteristics of the various types of apparatus is of great interest so that the number of experiments can be substantially reduced, and preselection and preliminary sizing can be carried out at a relatively early stage of process development.

The fluid-dynamic design of an apparatus is divided into the following areas:

1) Selection of suitable internals with respect to material of construction, shape, and size.
2) Determination of the operating conditions with respect to phase selection, pulsing, and loading.
3) Sizing of the column diameter in accordance with the required throughputs of feed and solvent.
4) Sizing of the column height in accordance with the actual separation problem.

However, these four problems cannot be considered in isolation. Thus, both the internals and the operating conditions affect (1) the loading limit and hence the column diameter and (2) the separation efficiency and thus the column height. Measures for increasing the loading limit have

an adverse effect on the separation efficiency, and vice versa.

Figure 26. Centrifugal extractors
A) Podbielniak extractor; B) Robatel four-stage countercurrent extractor

The sizing of the column diameter depends on the *flooding point*, i.e., the maximum loading limit at which a column can be operated. On flooding, accumulation of the dispersed phase occurs at individual points within the column and blocks countercurrent flow. Consequently, the light phase appears in the discharge of the heavy phase, and vice versa. This phenomenon is detectable by holdup measurements. On flooding, the holdup increases continuously and indicates an unstable operating state.

The flooding limit depends on the drop size. Small drops rise less rapidly than large drops and therefore cause a greater holdup. The more energy is supplied to the system – either by pulsing or by rotating internals – the smaller are the drops, so that the flooding limit decreases.

Internals also effect dispersing. The smaller their open area, the more the flooding limit decreases.

The sizing of the column height is determined by the mass transfer, which is described by the well-known mass-transfer equation: the rate of mass transferred is equal to the product of the mass-transfer coefficient, the mass-transfer area and the concentration difference between the two phases. A great progress in scientific research has been achieved as regards measurement and calculation of the quantities of influence on mass transfer (see for instance [6], [45–49], [51], [62–65], [68]. But in practice, the various influences on mass transfer are best summarized in the expression " height equivalent of a theoretical stage" (HETS), as a measure for the separation efficiency of the column, as mentioned in Section 2.5.

Measurements in pilot-plant columns will be used below to demonstrate the way in which various parameters affect the loading limit and separation efficiency. The test systems recommended by the European Federation of Chemical Engineering (EFCE) are used for this demonstration [44].

3.2.2. Operating Characteristics of Pulsed Columns and Columns with Rotating Internals

Loading Limit. Figure 27 shows the loading limit $v_C + v_D$ as a function of the pulsing frequency for plates of small free area φ for the toluene – water system, i.e., for high interfacial tension. v_c and v_d are the volume flows of continuous (c) and dispersed (d) phase related to the total cross-sectional area of the column, the so-called superficial velocities. This flooding point curve starts at the origin of the coordinates; in other words, without pulsing, no throughput is possible. With increasing pulsing, the throughput also rises up to a maximum. This part of the curve is called the lower flooding limit; here, pulsing has mainly a transport func-

tion. With increasing frequency, however, the dispersing function predominates, the drops become smaller and the loading limit falls. The interesting region in practice is that in which dispersing predominates.

Figure 27. Loading limit as a function of the pulsing frequency at different free area for toluene – water [50]
$a = 6$ mm; $v_d/v_c = 1$
△ $\varphi = 0.60$; $d = 6.5$ mm
□ $\varphi = 0.40$; $d = 4.0$ mm
○ $\varphi = 0.23$; $d = 2.5$ mm

As is to be expected, the loading limit rises with increasing free area over the entire pulsing range, but the position of the maximum remains unchanged. At the largest free area of $\varphi = 0.6$, a modest throughput is possible even without pulsing.

Figure 28. Loading limit as a function of pulsation frequency at different interfacial tension [50]: $\varphi = 0.23$; $v_d/v_c = 1$
a) Butanol – water: $\sigma = 1.8$ mN/m; b) Butyl acetate – water: $\sigma = 13.5$ mN/m; c) Toluene – water: $\sigma = 36.1$ mN/m

The effect of the geometry of the internals can also be shown for pulsed packed columns. There is no lower loading limit. At frequency $f = 0$, i.e., the unpulsed column, the loading limit has its maximum value, and decreases with increasing frequency [53].

Of all the physical properties, the *interfacial tension* has the greatest effect on the fluid dynamics of an extraction column. Figure 28 shows a comparison of three test systems with different interfacial tensions. As can be seen, the throughput optimum is shifted to higher pulsing frequencies with increased surface tension, i.e., high surface tensions need a high energy supply.

In addition to the physical properties, the phase ratio is another parameter determined by the process. Decisions can only be made as to which of the two phases is to be dispersed (the organic or the aqueous phase) and whether in the greater or smaller quantity. Figure 29 shows the effect of the parameter v_d/v_c [52]. As the phase ratio increases, the throughput decreases.

Figure 29. Relative loading of a pulsed sieve plate column as a function of flow ratio [52]
○ Toluene – water; □ MIBK – water; △ Butyl acetate – water; ◁ *n*-Butanol – water

A further parameter affecting the loading limit and separation efficiency is the direction of the mass transfer. Curve b in Figure 30 A shows the flooding point curve of the pure two-component mixture toluene – water, where no mass transfer takes place [54]. Curve a for mass transfer from the dispersed organic phase to the continuous aqueous phase lies substantially higher by comparison. The reason for this is an increased tendency to coalescence and hence formation of larger drops. In the converse case (mass transfer from the continuous to the dispersed phase), the interfacial tension and hence the drop size are reduced by the component

being transferred, leading to a lowering of the flooding point [53], [55]. The effect of the direction of mass transfer on the drop size also causes differences in the separation efficiency. In the case of mass transfer from the continuous phase to the dispersed phase (into the drop), smaller HETS values result, i.e., better separation efficiency is obtained (Fig. 30 B).

Figure 30. Influence of mass transfer on loading limit and separation efficiency for the toluene – acetone – water system ($\varphi = 0.60$)
△ Mass transfer from the disperse to the continuous phase; □ System without mass transfer; ○ Mass transfer from the continuous to the disperse phase

PILHOFER [56] has shown that the loading limit of extraction columns depends only on the drop size. Accordingly, high loading limits can be obtained only with relatively large drops.

Separation Efficiency. However to obtain a high separation efficiency a large mass transfer area, i.e., the greatest possible holdup of dispersed phase, is required. The holdup rises with decreasing drop size. Any input of energy has the purpose of producing the optimal drop dispersion. The interrelation of separation efficiency and pulsing can be demonstrated by measurements on the toluene – water – acetone system, which has a high interfacial tension [41]. Figure 31 shows the measured height of a theoretical stage (HETS) for this system as a function of the pulsation frequency, for the three different plate types (curves a – c). In all cases, the HETS decreases as expected with increasing pulsing intensity, i.e., pulsing enhances the separation efficiency. The curves show an important influence of the plate geometry: with increasing free area, the separation efficiency decreases sharply.

Figure 31. Separation efficiency measured as a function of interfacial tension [41]
a) – c) Toluene – water – acetone;
d) Butanol – water – succinic acid
+ $\varphi = 0.60$; ○ $\varphi = 0.40$; ▽ $\varphi = 0.23$

The butanol – succinic acid – water system shows very favorable HETS values because of its extremely low interfacial tension (curve d). The effect of free area is negligible. This means that, for systems of low interfacial tension, the free area can be increased in favor of higher throughputs, without a significant loss in separation efficiency.

A comparison of these two systems clearly shows the pronounced influence of the interfacial tension on separation efficiency. This fluid-dynamic aspect should also be taken into account when selecting solvents for extraction processes. Hitherto, this selection has been made almost exclusively under thermodynamic criteria.

The relationship between plate geometry, interfacial tension, and separation efficiency, as described here for a pulsed sieve plate column, qualitatively applies also to reciprocating-plate columns and pulsed packed columns. Generally speaking, in systems with a high interfacial tension, particular attention must be paid to the choice of the internals, a higher energy input is also necessary.

3.2.3. Fluid Dynamic Calculation Methods

The calculation methods for determining the loading limit can be classified in two categories. The first category consists of empirical correlations which are based on physical and geometrical data, and energy input. The second category is based on fluid-dynamic models and presupposes knowledge of the drop size. Both method classes are applicable only to two-component systems and thus neglect the effect of mass transfer, as shown in Figure 30. The effects of wetting and of drop coalescence are likewise disregarded. Moreover, the empirical correlations in particular are frequently restricted to certain geometries and cannot be extrapolated to other designs, they can therefore only be used to obtain an approximate estimate. For final equipment sizing, an experimental determination of the loading limit in the particular type of equipment with the original process streams is absolutely necessary.

Packed Column. Unpulsed packed columns have no industrial significance any longer. A review on empirical equations to calculate holdup, drop size, flooding, mass transfer, and axial dispersion is given in [6, Chap. 8]. Performance can be improved by mechanical pulsation of the continuous phase at the expense of a reduced throughput. For a rough estimate, pulsing within reasonable ranges may be assumed to cause the load limits to fall by 20 – 30 % as compared with the unpulsed column. Still, no equations for calculation are known.

Sieve Plate Column. The conventional sieve plate column has been investigated by Pilhofer [66] for toluene – water systems. Hirschmann [69] expanded the investigations of Pilhofer to liquid systems with lower surface tensions and density differences than toluene – water and to dual flow plates. For calculation see [69].

Sieve Plate and Rotating Columns. Special empirical equations are given in the literature for each type of extraction columns in order to calculate the flooding condition, so, e.g., for sieve plate columns in [66] and [67], for pulsed sieve plate columns in various chapters of [6], for rotating columns in [6] and [5]. However, since important effects are disregarded as mentioned before, here it will be sufficient to introduce a rough method based on a fluid dynamic model [66]. The model, originally developed for unpulsed sieve tray columns, proved to be applicable to all types of columns. It is assumed that the liquids occupy a share of the cross-section according to their holdup ε and flow toward each other as layers. If their superficial velocity v, i.e. their volumetric flow rate V related to the complete column cross section S, is

$$v_\mathrm{c} = \frac{V_\mathrm{c}}{S}\ ;\ v_\mathrm{d} = \frac{V_\mathrm{d}}{S} \tag{1}$$

they have an effective velocity $v_\mathrm{c}/(1-\varepsilon_\mathrm{d})$ or $v_\mathrm{d}/\varepsilon_\mathrm{d}$. That yields the relative velocity v_r, also called *slip velocity*, between the two liquids

$$v_\mathrm{r} = \frac{v_\mathrm{d}}{\varepsilon_\mathrm{d}} + \frac{v_\mathrm{c}}{1-\varepsilon_\mathrm{d}} \tag{2}$$

Either v_r or ε_d can be calculated from Equation (2) if one or more relationships between the two terms are known. In [45] a simple empirical equation is given to calculate v_r

$$\frac{v_\mathrm{r}}{v_\mathrm{p}} = (1-\varepsilon_\mathrm{d})^k \tag{3a}$$

$$k = 4.6 - 0.13 \ln Ar \tag{3b}$$

when $1 < Ar < 10^7$ and $2.5 < k < 4.6$

v_P is the individual drop velocity given by [66]

for *circulating drops*

$$Re_p = K_L^{0.15}\left(Ar^{0.523} K_L^{-0.1435} - 0.75\right) \tag{4a}$$

if

$$1.83\, K_\mathrm{L}^{0.275} < Ar < 3.94\, K_\mathrm{L}^{0.275}$$

for *oscillating drops*

$$Re_p = K_L^{0.15}\left(4.18 Ar^{0.218} K_{\mathrm{L}}^{-0.00773} - 0.75\right) \quad (4b)$$

if

$$Ar > 372.9 K_L^{0.275} \quad (4c)$$

The dimensionless numbers are defined as follows:
particle Reynolds number

$$Re_{\mathrm{p}} = \frac{v_{\mathrm{p}} d_{\mathrm{p}}}{\nu_{\mathrm{d}}} \quad (5)$$

Archimedes number

$$Ar = \frac{d_{\mathrm{p}}^3 g \varrho_{\mathrm{c}} \Delta\varrho}{\eta_{\mathrm{c}}^2} \quad (6)$$

characteristic number of liquid

$$K_{\mathrm{L}} = \frac{\varrho_{\mathrm{c}}^2 \sigma^3}{\Delta\varrho g \eta_{\mathrm{c}}^4} \quad (7)$$

density difference

$$\Delta\varrho = |\varrho_{\mathrm{c}} - \varrho_{\mathrm{d}}| \quad (8)$$

Mathematical formulation implies the fact that an increase of the flow rate at flooding cannot increase the drop holdup:

$$\frac{\mathrm{d}v_{\mathrm{d}}}{\mathrm{d}\varepsilon_{\mathrm{d}}} = 0 \quad (9a)$$

when v_{c} = constant,

$$\frac{\mathrm{d}v_{\mathrm{c}}}{\mathrm{d}\varepsilon_{\mathrm{d}}} = 0 \quad (9b)$$

when v_{d} = constant.

With Equation (2) for the slip velocity v_{r} the equations for calculating the superficial velocities v_{c}, v_{d} at the flooding point are obtained in a dimensionless form:

$$v_{\mathrm{c}}\left(\frac{\varrho_{\mathrm{c}}}{\Delta\varrho v_{\mathrm{c}} g}\right)^{1/3} = Ar^{-1/3}(1-\varepsilon_{\mathrm{d}})^2\left(Re_{\mathrm{r}} + \frac{\varepsilon_{\mathrm{d}}\,\mathrm{d}Re_{\mathrm{r}}}{\mathrm{d}\varepsilon_{\mathrm{d}}}\right) \quad (10a)$$

$$v_{\mathrm{d}}\left(\frac{\varrho_{\mathrm{c}}}{\Delta\varrho v_{\mathrm{c}} g}\right)^{1/3} = Ar^{-1/3}\varepsilon_{\mathrm{d}}^2\left(Re_{\mathrm{r}} - (1-\varepsilon_{\mathrm{d}})\frac{\mathrm{d}Re_{\mathrm{r}}}{\mathrm{d}\varepsilon_{\mathrm{d}}}\right) \quad (10b)$$

Equations (10a) and (10b) together with Equation (3) for v_{r} and Equation (4) are the basis for flooding point diagrams according to Figure 32. Ordinate and abscissa contain the superficial velocities v_{d} and v_{c}, i.e., the phase flow rates, modified by physical data groups to a dimensionless form. The diagram shows the calculated flooding curves of *circulating* drops as solid lines with the parameter Ar. Dashed lines of constant phase ratio $v_{\mathrm{d}}/v_{\mathrm{c}}$ and the total throughput as the sum of v_{d} and $v_{\mathrm{c}}$are also shown.

Figure 32. General loading diagram [52], [56]

It can be seen from Equation (4b) that Re_{P} is approximately proportional to $Ar^{0.3}$ and therefore to d_{P}. That means that the drop velocity v_{P} is nearly independent of drop diameter d_{P} in the region of oscillating drops. Therefore Figure 32 can be used also for *oscillating drops* if Ar is replaced by K_{L} using Equation 4c. Otherwise the diagram is valid for a certain K_{L} value in the region of circulating drops, in case of Figure 32, $K_{\mathrm{L}} = 10^{11}$.

The dependence of drop diameter d_{P} upon parameters of influence must be known in order to use Figure 32 and to calculate flooding curves. Many scientific investigations on drop disintegration in various extractors are found in the literature, but often without considering the influence of mass transfer and the interaction of dispersing and coalescence. Furthermore, particularly for higher interfacial tension systems a considerable height of column is required to reach a steady-state drop size, and this height varies with liquid system and inlet arrangement for the dispersed phase. Since population balances are not used in this introductory article,

the concept of mean drop sizes is applied – normally reported as the Sauter mean or surface percentage mean drop size – defined by

$$d_{32} = \frac{\sum_i n_{\mathrm{p}i} d_{\mathrm{p}i}^3}{\sum_i n_{\mathrm{p}i} d_{\mathrm{p}i}^2} \tag{11}$$

where $n_{\mathrm{p}i}$ represent the numbers of drops of the class i of diameter $d_{\mathrm{p}i}$.

Finally, discussion will be restricted to empirical equations by KUMAR and HARTLAND [6, Chap. 17] which give the best fit to experimental data and have the broadest range of validity:

Pulsed sieve tray and reciprocating extractor

$$\frac{d_{32}}{\sqrt{\frac{\sigma}{\Delta\varrho g}}} = C_1 e^{0.74} \left(\frac{h}{0.05\mathrm{m}}\right)^{0.10} \cdot \left[\exp\left(-3.00\frac{af\Delta\varrho^{1/4}}{g\sigma^{1/4}1/4}\right) + \exp\left(-28.65\frac{af\Delta\varrho^{1/4}}{g\sigma^{1/4}1/4}\right)\right] \tag{12}$$

The best values of the parameter C_1 are 1.51, 1.36, and 2.01 for no mass transfer, c → d, and d → c direction of transfer, respectively. The product $a \cdot f$ is considered as the agitation variable in the equation, since the fit could not be improved if a and f were treated separately. The average absolute value of the relative deviation in the predicted values of d_{32} from the experimental points is 16.3 %.

Rotating disk extractors

$$\frac{d_{32}}{D_{\mathrm{R}}} = \left(\frac{C_1}{0.07 + \sqrt{Fr_{\mathrm{R}}}}\right)\left(\frac{\eta_{\mathrm{c}}}{\sqrt{\sigma\varrho_{\mathrm{c}}D_{\mathrm{R}}}}\right)^{-0.12} \left(\frac{\varrho_{\mathrm{d}}}{\varrho_{\mathrm{c}}}\right)^{0.16} \cdot \left(\frac{D_{\mathrm{R}}^2\varrho_{\mathrm{c}}g}{\sigma}\right)^{-0.59} \left(\frac{h}{D_{\mathrm{C}}}\right)^{0.25}\left(\frac{D}{D_{\mathrm{R}}}\right)^{0.46} \tag{13}$$

The optimized values of C_1 are 0.63, 0.53, and 0.74 for no mass transfer, c → d and d → c directions of transfer, respectively. The effect of holdup is ignored due to lack of data. Equation (13) predicts the drop size with an average absolute value of the relative deviation of 23 %.

Kühni columns

$$\frac{d_{32}}{D_{\mathrm{R}}} = C_1 e^{0.37} n_{\mathrm{S}}^{-0.11} \left[0.14 + \exp\left(-18.73 Fr_{\mathrm{R}}\right)\right] \cdot \left(\frac{\eta_{\mathrm{c}}}{\sqrt{\sigma\varrho_{\mathrm{c}}D_{\mathrm{R}}}}\right)^{-0.20}\left(\frac{D_{\mathrm{R}}^2\varrho_{\mathrm{c}}g}{\sigma}\right)^{-0.24} \tag{14}$$

The values of the constant C_1 are 9.81×10^{-2} for no mass transfer and c → d transfer and 0.31 for d → c transfer. The stage number n_{S}, which varies from 2 to 17 in the present set of data, shows a rather weak effect on drop size. Equation (14) predicts the drop diameter with an average absolute value and relative deviation of 17.6 %.

3.3. Apparatus Design

Extraction apparatus can be approximatively designed purely by calculation using fluid-dynamic models [49], [70]. For reliable design, however, pilot-scale tests are indispensable. If possible, the test should be carried out with the original operating mixture in the type of apparatus which is also envisaged for the large-scale unit. Desirably, the geometry of the internals should be the same in the pilot-scale and industrial apparatus. However, this condition cannot always be satisfied. Generally, a column diameter of at least 60 – 80 mm is necessary for design tests. Tests in smaller columns cannot be used as the basis for equipment sizing (for criteria on equipment selection, see Section 3.4). The number of tests can, however, be substantially reduced if knowledge of the operating characteristics is utilized.

The physical data and the phase ratio are determined by the process used, the following parameters are available for optimization: pulsing or rotation, geometry of the internals, material of the internals, and phase selection, i.e., the direction of mass transfer. Energy input and the geometry of the internals are selected on the basis of the physical data.

3.3.1. Internals and Operating Conditions

The following guidelines apply for the selection of the free area in pulsed columns. An increase in the free area is recommended in systems with a low interfacial tension where it leads to a great reduction in the column volume. At moderate interfacial tension, the column diameter can be reduced by a greater free area, but at the expense of the column height. In the case of extremely

Case		Dispersed phase	Location of interface	Arrangement	Plate material
1 Aqueous feed	$\rho_F > \rho_S$	Org. solvent	Head		Metal
2 Aqueous feed	$\rho_F < \rho_S$	Org. solvent	Bottom		Metal
3 Organic feed	$\rho_F > \rho_S$	Water	Head		Plastics
4 Organic feed	$\rho_F < \rho_S$	Water	Bottom		Plastics

Figure 33. Selection of phases and plate materials

high interfacial tension, there is no point in increasing the free area.

The material of the internals should be selected so that the continuous phase, but not the dispersed phase, wets the plates. As a rule of thumb, metal plates can be used when the organic phase is dispersed; if the aqueous phase is dispersed, the internals should be of plastic, both in pulsed columns and in rotary-agitated columns.

In deciding which phase should be dispersed, the direction of mass transfer must be taken into account. In accordance with Figure 30, mass transfer should be from the continuous phase to the dispersed phase, if possible. In the final phase selection, however, fluid-dynamic considerations frequently conflict with operating and safety requirements. The position of the interface in the column determines the phase which is dispersed. Figure 33 summarizes the possible combinations.

The separation efficiency determines the column height and the load limit determines the column diameter. For optimization, the two parameters are related by the ratio $\theta = \text{HETS}/(v_c + v_d)$ which can be used to optimize the column internals and energy input. A minimum value of this expression is equivalent to a minimum column volume. Figure 34 shows that optimum pulsing is obtained between the maximum of the flooding point curve and the minimum of the HETS curve. An analogous procedure is used for rotary agitated columns. The design point for industrial-scale columns is chosen to be 75 – 80 % of the load limit. The operating point with respect to load and pulsing (rotation) is fixed by this procedure.

3.3.2. Column Diameter

Assuming the same column geometry, the specific throughput of the test column is adopted for the large-scale column.

$$(v_c + v_d)_2 = (v_c + v_d)_1$$

with

$$(v_c + v_d)_1 = 0.75 \cdot (v_c + v_d)_{1\max}$$

Index 1 = pilot scale
Index 2 = large scale

This gives the column diameter:

$$D_2 = \sqrt{\frac{4\left(\frac{\dot{m}_F}{\varrho_F} + \frac{\dot{m}_S}{\varrho_S}\right)_2}{\pi \cdot (v_c + v_d)_2}}$$

Figure 34. Optimization of pulsation

3.3.3. Column Height

The separation efficiency of all columns decreases with increasing column diameter, because the residence time distributions of the phases increase. Therefore values of the height of a theoretical stage, measured for a laboratory column, need to be corrected by empirical scale-up equations to be applicable for industrial-scale columns. However, scientific investigations of this problem are rather poor and mainly empirical knowledge of industrial engineers exists. The different chapters of [5] list formulae from experience with countercurrent extractors as described here, including

Pulsed sieve tray columns [71]

$$\frac{\mathrm{HETS}_2}{\mathrm{HETS}_1} = \exp\left[1.64\,(D_2 - D_1)\right] \tag{15}$$

(in Equation 15 the factor 1.64, given by THORNTON, is only valid for small columns. Figure 35 shows an empirical dependence of the Thornton factor from the column diameter published by REISSINGER [49])

Reciprocating columns [72]

$$\frac{\mathrm{HETS}_2}{\mathrm{HETS}_1} = \left(\frac{D_2}{D_1}\right)^{0.38} \tag{16}$$

When the plate geometry and amplitude of the vibration are left unchanged in the large-scale column, the frequency should be reduced, according to:

$$\frac{f_2}{f_1} = \left(\frac{D_1}{D_2}\right)^{0.14}$$

The following applies to stirred columns [73]:

$$\frac{\mathrm{HETS}_2}{\mathrm{HETS}_1} = \left(\frac{D_2}{D_1}\right)^{0.33}$$

Figure 35. Dependence of Thornton factor on column diameter

3.4. Criteria for Equipment Selection

For a given separation problem, equipment is selected essentially according to three criteria: physical properties, required number of separation stages, and throughput. Further operating aspects are frequently important, for example, flexibility regarding load variations or product quality, sensitivity to small amounts of solids, suitability for batch operation.

The physical properties of interest in extraction are the density difference between the two

Figure 36. Comparison of the number of theoretical stages NTS in dependence of total load for Kühni, QVF, Karr and pulsed sieve plate extractors (PSE) [64] (system butyl acetate – water – acetone, phase ratio $v_d/v_c \approx 1.12$, measurements of various authors cited in [64])

phases, their viscosity, and interfacial tension. These three parameters affect dispersibility and phase separation behavior.

High density difference, viscosity, and interfacial tension make dispersing more difficult; systems with such physical properties require a higher dissipation of energy than in the converse case. Phase separation is favored by a high density difference and interfacial tension, whereas a high viscosity makes phase separation more difficult.

The lower limit for the density difference can be taken to be 50 kg/m^3. Mixtures with higher density differences can generally be processed in columns and mixer – settlers. If the density difference is smaller, a centrifugal extractor must be used.

A low interfacial tension leads to phase separation problems. In industrial units, approximately $\sigma = 1 - 2$ mN/m can be taken as the lower limit. Therefore, mixer – settlers can certainly not be used for mixtures of relatively low interfacial tension; because of the shear field generated, centrifugal extractors also have a dispersing effect which should not be underestimated. In such cases, the energy input must be very carefully controlled. Rotary-agitated columns and pulsed columns can be used, in which the energy input can be adapted to the physical properties by the speed of rotation or the pulse frequency.

The selection of equipment is also affected by the number of theoretical stages (NTS) required for a given separation problem. Only small numbers of theoretical stages can be achieved in columns without energy input, because of their poor separation efficiency. Pulsed columns and rotary agitated columns give higher numbers of separation stages. They are limited by the pulsing units or by the lengths of the continuous shaft. In centrifugal extractors, the Robatel design provides more separation stages than, for example, the Podbielniak extractor. Mixer – settlers are constructed in modules so that there is virtually no limit to the number of separation stages.

A first estimate of the maximum possible throughputs in the individual extractor types can be obtained by considering the largest diameters (D_{max}) which have hitherto been installed:

	D_{max}, m
Reciprocating-plate column	1.5
Pulsed column	2.7
Kühni extractor	2.5
QVF extractor	2.8
Rotating Disk Extractor	3.0
Mixer – settler tower	8.0

Figure 37. Comparison of efficiency versus load of packed columns with and without pulsing and pulsed sieve tray extractors $a \cdot f$ = pulsation intensity, B_f = flooding load, φ = relative free area

Accordingly, the highest throughputs can clearly be achieved with the mixer – settler. In pulsed columns, the diameter is limited by the pulsing unit. In rotation columns, the separation efficiency at large diameters is no longer satisfactory. However, informations about maximal cross-sectional loads which are necessary to obtain definitive throughput data of a type of extractor are not given in the list.

The literature contains some publications which recommend criteria for the selection of the best apparatus. However, most of these recommendations are only qualitative, and some are even contradictory; no studies of apparatus have so far allowed an objective comparison. Only the standardization of test systems for extraction has allowed fluid-dynamic studies to be carried out under comparable conditions [44]. The following systems have been recommended:

Toluene – water – acetone
Butyl acetate – water – acetone
Butanol – water – succinic acid

These systems provide an objective basis for comparison of equipment. Nevertheless, investigations by different authors are not always mutually comparable with respect to the absolute HETS values. Evidently, the column length and the phase ratio have an unexpectedly large effect.

For the toluene system, Pilhofer compared the different operating characteristics of various groups of equipment. Analogous studies on the liquid system butyl acetate – water – acetone were carried out by Goldmann [64]. Figure 36 shows a diagram of Goldmann with the number of theoretical stages NTS per meter of column height, as a function of the load. The figure contains data for QVF and Kühni columns – the latter with five different free areas of the perforated partition disks – and for pulsed sieve plate extractors (PSE) with five different free areas φ and one reciprocating column (Karr). The rotary agitated columns of QVC and Kühni with the smallest free areas φ clearly achieve the highest NTS values, but allow only low loads. Also, the other Kühni columns show higher NTS values than the

pulsed columns but smaller ranges of load. Generally speaking, all measures which improve the separation efficiency reduce the load capacity.

A comparison between pulsed sieve trays and structured packings with the test system toluene – water – acetone was published [74]. Figure 37 shows the diagram with the extractor efficiency in dependence on the load. It is obvious that structured packings have the broadest range of load capacity and reach the same or higher efficiencies as pulsed sieve trays. From the results for two structured packings without pulsation the positive influence of pulsing can clearly be seen: The pulsed unstructured packing, Pall rings 15 × 15 mm, has a clearly smaller load range.

In Figure 38, the range of loads is compared for sieve trays and structured packings with pulsation [75]. According to that, packed columns have significant advantages. As shown in [75], the investment costs of pulsed structured packed columns are 30 % lower than the ones of pulsed sieve tray columns and 40 to 50 % lower than pulsed unstructured packed columns.

Figure 38. Range of load of pulsed structured packed columns in comparison to pulsed sieve tray columns in dependence of the mass density difference for aqueous systems and systems similar to water

In [76] a systematic study on extractor selection is given.

Adaptation of the Column Geometry to the Separation Problem. In the early days of extraction, various types of apparatus were restricted to clearly defined geometries and were thus sharply distinguished from one another. Recent apparatus developments allow adaptation of the column geometry to physical data, both for pulsed columns and rotary-agitated columns. The boundaries are thus no longer distinct and a general fluid-dynamic description of related types of apparatus is feasible. The optimization of operating conditions and the geometry of the internals is as equally important as the selection of a suitable type of apparatus.

In practice the final selection of equipment is often based on product-specific conditions or plant requirements which include sensitivity to solids, tendency of the product to polymerize, and safety aspects, for example with regard to solvent holdup.

Untypical Operating Conditions. Usually extractors operate with nearly the same volume flow for both liquids and for liquids with viscosities similar to that of water. Therefore, the equations given before are only valid for such conditions. Some approaches for untypical operating conditions are given below.

Rauscher [62] investigated pulsed sieve tray extractors with phase ratios between 0.06 and 10 and the liquid system *n*-butyl acetate (o) – water (d) – methyl isopropyl ketone (MIPK), which enriches MIPK in equilibrium preferable in the organic phase. He confirmed the experience that the separation efficiency declines for phase ratios unequal 1 and found the following causes: By dispersion of the smaller volume flow (phase ratio $\ll 1$), stronger backmixing of droplets by the continuous phase will occur, leading to a broader drop size distribution. By dispersion of the larger volume flow (phase ratio $\gg 1$), the wake behind the drops causes remarkable backmixing of continuous phase. These phenomena have to be taken into account by an adequate calculation via drop population balances.

G. Wagner [58] investigated the fluid dynamics of pulsed sieve tray and Kühni rotating extractors using liquid systems with viscosities up to 50 mPa · s, mixed from paraffin oil and *n*-hexane as organic phase and of glycerol and water as aqueous phase. I. Wagner [77] continued the work with mass transfer investigations using the system tridecanol as drop phase ($\eta = 42$ mPa · s), water, and propanol. The experiments showed that the mean Sauter drop diameter increases with increasing drop viscosity; holdup is decreased, while the flooding curve is shifted to higher throughputs. In case the

continuous phase is the more viscous one, the drop swarm contains a larger fraction of small droplets causing increased droplet entrainment by the continuous phase. In stirred columns, the drop size can be influenced in a broader range than in pulsed columns; yet, more energy will be required for a certain drop dispersion. Intensive stirrers as in Kühni and QVF extractors should be preferred to stirrers in RDC extractors.

In the case of a more viscous continuous phase, the drop dispersion is nearly independent of drop viscosity and is hardly influenced by the rotating or pulsating internals. Here, lower intensity dispersers are preferable, such as RDC extractors.

The mass transfer to drops is distinctly decreased by increasing drop viscosity, developing towards the state of transfer to rigid spheres, and depends on the contact time. It can be improved by suitable internals and by supply of energy.

4. Phase-Separation Equipment

4.1. Gravity Settlers without Inserts

Each extraction stage consists of two steps: (1) dispersing and (2) phase separation by coalescence of drops, thus generating a homogeneous layer of drop phase. Figure 39 A shows a vertical settler at the top of a column for the case that the drop phase has a lower density than the continuous phase. The drops rise against the sinking continuous liquid and are blocked by the upper level of the continuous phase, which is the principal interface. There, coalescence of the dispersed phase will occur both between adjacent drops and at the principal interface. The coalesced drop phase leaves the extractor at the top of the column.

In a horizontal settler, as shown in Figure 39 B, both phases flow in the same direction. Drops of lighter dispersed phase rise to the interface where they coalesce to form a homogeneous layer. In the lower part of the settler a layer of the continuous phase remains, growing in flow direction due to decreasing drop numbers. The wedge-shaped zone of dispersion should end before the placement of phase outlets.

As the accumulation of impurities in technical liquid systems changes important properties such as viscosity and surface tension, an exclusively theoretical modeling, as developed by many authors (see for instance [80]), is insufficient. However, the length of a horizontal settler can be estimated by a combined procedure of calculations and simple and cheap batch settling experiments [79]. The calculation is based on a model of the physical processes in a settler, while experiments supply one empirical parameter to include surface phenomena that could not be modeled so far (see Figs. 40 and 41).

A glass cylinder as shown in Figure 40 A, filled with about 1 L of the original liquid – liquid system, is vigorously shaken for 1/2 to 1 min. After placing it in an upright position, the heights of sedimentation and coalescence fronts are measured in dependence of time as shown in Figure 40 B for drops being lighter than the continuous phase. The drops are banked up in a dense layer if sedimentation is faster than the drop coalescence. The curves of sedimentation and coalescence meet each other at time t_e when all drops are coalesced. For a sufficient reproducibility of measurements it should be made sure that the glass flask is washed with deionized water, that the distribution of drop sizes is narrow and the temperatures of the liquid – liquid system in the glass cylinder and the continuous settler are equal [78]. Figure 37 C shows the height H of the wedge-shaped zone between the curves of sedimentation and coalescence.

The concept of settler dimensioning is shown in Figure 41. All equations mentioned in the following are given in [79]. Settler dimensioning starts with evaluation of settling experiments according to Figure 41 A. The linear curve of sedimentation supplies the velocity of sedimentation; a model of drop swarm sedimentation supplies the diameter of the starting drop swarm [66]. The thickness of the dense layer of drops follows from a balance of sedimenting and coalescing drops in time steps. The next stage is calculation of drop deformation in vertical steps [80]. This serves to calculate coalescence times between drops and between drops and their homophase, the former to determine the drop growth, the latter to calculate the drop homophase formed by coalescence [80]. The coalescence model contains a fitting parameter F_p to fit the calculated and measured coalescence curve in Figure 41 B. This parameter is the link between the settling experiment and the settler

Figure 39. Vertical (A) and horizontal (B) gravity settlers for drop separation from a continuous liquid

Figure 40. Experiments on batch settling

dimensioning; F_p can be used for the settler calculation, given in Figure 41 B.

The settler needs an inlet length L_{in} which can be calculated by a model equation in dependence on settler diameter, operation parameters, and the mean drop size at the settler inlet, coming from the extractor outlet. For calculation of coalescence in the dense drop layer the same equations that were modeled for the settling experiment can be applied using the fitting parameter F_p derived from these experiments. The result is the geometry of the wedge of dispersion, i.e., its height and length, which has to be taken into account for dimensioning the settler.

This combined experimental and theoretical procedure yields good results although the drop distributions in the settling experiment and the real settler are not the same. The extensive equation system needs computer aided solving. A computer program is offered by [81]. A simplified method is given in [79].

4.2. Settlers with Coalescing Aids

Gravity settlers are often equipped with coalescing aids to fit a settler to special conditions of the liquid system or of the operational behavior. Industrially proven coalescing aids are inclined or corrugated plates, fixed beds of small packings, fiber beds, porous sintered materials, and membranes. In some cases, when the drop sizes to be settled are smaller than 1 µm or if surfactants render the settling more difficult, centrifuges [6, Chap. 8] or electrical fields must be applied [82]. The most important coalescing aids are inclined packages of plain or corrugated plates and fiber bed filters.

Figure 41. Dimensioning a continuous settler [79]
A) Evaluation of settling experiments; B) Fitting of measured and calculated curve

Inclined Plates. Figure 42 shows one possible arrangement of inclined plates in a horizontal settler. Other plate configurations are possible. In any case, the feed has to be distributed by a sieve plate at the settler entry over the cross-sectional area, filled with inclined plates. The plates shorten the sedimentation distance of drops and provide a larger interfacial area for the coalescence. The drops coalescing at the plates form trickling films which flow off to the horizontal, principle interface due to a hydrostatic pressure difference. A plate material wettable by the drop phase is a prerequisite. Several scientific investigations and experiments with liquid systems of a wide range of properties were made during the 1970s and 1980s on the hydrodynamics of inclined films and the coalescence of drops at the film surface, these are summarized in [83–86]. The main results are:

1) Thin laminar films should flow on the plates, because the coalescence of drops is promoted by the shear stress of film flow near the plate; the larger the volume flow of cocurrent continuous phase, the smaller the film thickness and the better the coalescence.
2) The plate should be wettable by the drop phase (advancing contact angle $< 70°$, receding contact angle $> 15°$).
3) The drop swarm has to be distributed equally over the width of plates.
4) Constructions that can thin the trickling film increase the settler performance.

5) Short lengths of plates of about 400 mm are sufficient for coalescence of drops riding on the film.
6) The width b_p of a plate can be calculated by the empirical equation of the Reynolds number of trickling film

$$Re_f \leq 80 K_{L,d}^{0.19}$$

$$b_p = 0.03 \frac{V_d}{(Re_f k v_d)^{3/2}} \left[\frac{\Delta \varrho g \sin\alpha}{\eta_d} \right]$$

with the liquid number of trickling film

$$K_{L,d} = \frac{\sigma^3 \varrho_d}{g \eta_d^4} \frac{\varrho_d}{\Delta \varrho}$$

where α is the plate inclination, $V_{d,1} = V_d/n$ the volume flow of dispersed phase on a plate, and n the number of plates.
7) The optimum of plate inclination is within the range $10° < \alpha < 15°$.
8) The distance of adjacent plates should not be smaller than 30 to 40 mm in order not to disturb film flow and drop coalescence.
9) The trickling film continuously carries surfactants to the outflow of a plate and thus prevents their accumulation. Therefore surfactants hardly influence coalescence and settling performance up to medium flow rates of drop phase.
10) Under certain conditions, the drop coalescence leaves very small droplets, so-called secondary drops, due to partial coalescence, which generate a droplet entrainment at the settler exit. Its occurrence is primarily a question of liquids involved, i.e., their viscosity ratio [86].

The coalescence time of secondary drops is significantly higher than that of primary drops, due to interfacial effects. Settling of secondary drops requires other coalescers, for instance membrane coalescers or centrifuges.

Fiber bed filters are built from short fibers stuffed to rectangular mats or to disks of 15 to 25 mm thickness, held in a suitable support, or from fiber fleeces as shown in Figure 43.

They have a definite, large voidage of about 95 %, nevertheless they are sensitive to solid dirt particles in the liquid. The droplets couple to the fibers while flowing through the fiber bed, succeeding drops coalesce with them and enlarge the size of adhering drops until the liquid flow pulls them out of the bed due to increasing flow resistance. A fiber bed is able to enlarge the sizes of incoming drops at least by one order of magnitude so that they can coalesce in a subsequent settler with their homophase. Fiber bed filters are restricted to drop concentrations < 10 vol % to avoid redispersion.

Rebelein [87], [88] and Magiera [89], [90] defined heuristic rules for the design of fiber beds on the basis of careful experiments with a broad variation of parameters of influence:

1) Fiber materials as glass or stainless steel with high energetic surfaces provide different interaction sites (e.g., hydrogen bonds and ion – dipole interaction) for the liquid and improve the fiber bed performance compared to materials with low energetic surfaces as for instance teflon. High energetic surfaces improve the wetting properties of the fibers.
2) The drop enlargement in a fiber bed decreases with increasing flow rate, i.e., with superficial velocities > 1 cm/s.
3) Small fiber diameters of about 15 µm are favorable.
4) The bed depth required for coalescence increases with the fiber diameter.
5) The concentration of droplets in the incoming liquid hardly influences the bed performance.
6) Best efficiency means a separation of about 95 % of incoming drops.
7) The larger the surface tension of the liquid system, the better the separation performance.
8) Smallest drop sizes that can be separated are about 10 µm.
9) Presence of surfactants and mud and a higher viscosity of the continuous phase reduce the separation performance, the viscosity of the drop phase has no influence within 50 and 5000 mPa · s.

All attempts to calculate the bed performance in advance via filter coefficients were fruitless [87–90]. Magiera developed a mathematical model of physical mechanisms inside a fiber bed and was able to simulate the bed behavior and drop enlargement by introduction of two experimental fitting parameters. Therefore, a reliable dimensioning of fiber beds needs experiments

Figure 42. Horizontal gravity settler with two inclined packages of plane, parallel plates. The height of principal interface is best situated, when both phases have the same exit velocity

Figure 43. Combined fiber bed coalescer and gravity settler

with the liquid dispersion which is to be separated.

Figure 44. Membrane coalescer [91]

Membrane Coalescence. A new and very promising method to separate fine droplets down to 1 μm from emulsions, stabilized by surfactants, was discovered and investigated by HOFFMANN [91] (Fig. 44).

Membrane coalescers are applicable in a broad range of volume concentrations down to a lower concentration limit of the organic phase (0.1 vol %). A thin, hydrophobic, stretched membrane, for instance polytetrafluoroethylene (PTFE), held in place by a support, is permeated by two-phase flow of emulsion. The emulsion leaves the membrane as a liquid foam with large oil domains which will immediately coalesce at the principle interface in a succeeding settler. A superficial velocity through the membrane is possible within the range of 0.1 to 19 cm/s, the pressure drop is comparable with that in fiber beds. The main advantages are huge separation performances of about 98 %, in combination with a large range in throughput; the

ability to separate droplets one order of magnitude smaller than in fiber beds; and the insensitivity against hydrophobic surfactants. Hydrophilic surfactants are without influence, too, if their amount is clearly lower than the critical micelle concentration.

Selection of Appropriate Settler. Most important and the first step in selection of a settler is a careful analysis of separation problems [78], [92]. The flow sheet of the complete process can give hints on origin and kind of the dispersion to be separated. Sometimes the preceding steps could be altered in order to simplify the phase separation problem. Measurements of properties of the liquid system and settling experiments in a glass cylinder show, if and why a phase separation can be problematic. Drop sizes smaller than 100 µm need suitable coalescing aids which are supposed to be well wettable by the drop phase. When the drop settling in a glass cylinder is fast, but the liquids appear cloudy, this indicates partial coalescence, resulting in very fine drops, so that a fiber bed or a membrane coalescer will be necessary.

The presence of solid particles and mud requires filters before the settler. The wetting behavior of coalescing aids can significantly change the operation of the process. This should be accounted for in the procces. The phase ratio can be changed by recycling of one phase to the settler. By this, the type of dispersion can be inverted. In case the organic phase has a higher viscosity than the water phase, an o/w dispersion separates much better than a w/o dispersion, and vice versa.

5. Liquid – Liquid Extraction Processes

5.1. General

The quality of the *raffinate* in liquid – liquid extraction can be controlled easily by changing the ratio of solvent to feed and the extraction temperature. The quality of the *extract* is governed only by the conditions of feed location and no direct control is possible.

This is especially true because most extractions are carried out in a closed system to minimize solvent requirements. In such a system, a maximum extract purity is obtainable and some components that should end up in the raffinate leave with the extract.

Additional steps are, therefore, required to enhance extract purity and thus raffinate yield. If the extract is the product desired, improving extract purity is the most important – in fact, the only – objective. Different solutions to this problem are applied in commercial operation.

Change in Temperature. Extract purity can be increased by cooling the extract from the main system and adding one more stage (see Fig. 45 A). In the triangular diagram, this means that the binodal curve is changed from a to b (Fig. 45 B).

Because the composition of the first extract is now inside binodal curve b, it separates in a settler b in a purer final extract phase and a small amount of intermediate raffinate phase. The latter is returned to the main extraction system.

The selectivity of separation in the additional stage is not very great because the loading of the first extract phase is rather high and separation takes place near the plait point. This system can be used when the main system is operated at high temperature for other reasons or when an increase in extract purity and the resultant increase in raffinate yield are desirable.

Addition of Water. The addition of water at or below the feed point generally changes the system from a closed to an open one (see Section 2.1.1.). In this way, extract purity can be increased to the required level. Water is soluble, at least to some extent, in most polar solvents and therefore leaves the system with the final extract phase. In this way, no unwanted influence is exerted on the main extraction system.

However, because water must be separated from the solvent by distillation before its reintroduction in the main extractor, the heat requirements are high. Addition of water is, therefore, not regarded as a generally attractive solution. Also, water can only be added when its boiling point is much lower than those of the solvent and the feedstock.

Use of a Countersolvent. As shown in Figure 46, a second solvent can be fed into one end of the extraction system, on the opposite side of

Figure 45. Use of cooling stage
A) Process flow scheme: a) Extractor; b) Settler
B) Triangular diagram: a) Binodal curve at higher temperature; b) Binodal curve at lower temperature

the solvent entry point. The feed in this case is introduced somewhere in the middle of the system.

Figure 46. Extractor for separation using a countersolvent
(a) Extractor

The countersolvent should be only slightly soluble in the solvent and, therefore is generally similar in chemical structure to the key component of the raffinate phase. The boiling point of the countersolvent should be such that it can easily be separated by distillation from the solvent as well as from the raffinate and the extract (i.e., either a much lower or a much higher boiling point). Because the countersolvent does not contain any raffinate components when it enters, it can wash out the raffinate components in the solvent at the feed point.

Additionally, some extract components are washed back by the countersolvent, thus increasing the load in the top section. In this way, a very pure final extract can be produced, depending on the ratio of countersolvent to feed used.

A disadvantage of this system is that the countersolvent enters the top section. Consequently, the phase ratio of B-rich to A-rich phase is reduced, resulting in a less pure raffinate (this also means a lower yield of extract). To restore raffinate purity, more B-rich phase must be applied. Such a system is thus costly and sensitive to changes in feed composition, solvent-to-feed ratio, and ratio of countersolvent to feed.

Some improvement can be obtained by carrying out the extraction in two parts (Fig. 47).

In the first extractor (a), the feed is extracted with the primary solvent. The intermediate extract phase is fed to a second extractor (c) and

brought in contact with the countersolvent. The mixture of countersolvent and intermediate raffinate is fed to a column (b) in which the intermediate raffinate and the countersolvent are separated by distillation. The pure intermediate raffinate is then fed to the first extractor, while the countersolvent is charged to the second extractor. In this way, some of the disadvantages can be overcome.

Figure 47. Use of countersolvent with intermediate recovery
a) First extractor; b) Distillation column; c) Second extractor

5.2. Combined Processes of Extraction and Distillation

Azeotropic Distillation. Usually it is necessary to combine extraction and distillation processes for recovering the solvent from the extract phase and also from the raffinate phase, if the solvent is soluble in the raffinate.

Figure 48 shows as an example the recovery of acetic acid from an aqueous solution with methyl *tert*-butyl ether (MTBE) as solvent. The system of water and acetic acid is a highly nonideal azeotropic mixture that could be separated by simple distillation. However, for dilute feed compositions solvent extraction is more advantageous because of the very high energy demand of a water-rich feed distillation. The triangular diagram of Figure 48 shows that the binary system of solvent MTBE and water has a heterogeneous azeotrope. As a consequence, extraction has to be combined with azeotropic distillation as shown in the flow sheet of Figure 48 B. By extraction in the extractor E extraction feed F is changed to raffinate R and the solvent L1 to extract phase F1, which on the other hand is the feed of distillation column C-1. In C-1 the extract is split into the bottoms acetic acid B1 and an acetic acid-free distillate D1 connected by the main balance line of distillation in the triangle diagram. The acetic acid-free raffinate R is fed into column C-2 where it is separated into the bottoms, pure water B2 and water – MTBE azeotrope D2. Both distillates D1 and D2 lie in the immiscible region between MTBE and water. This makes simple decantation (S) of the condensed phases possible. The solvent-rich fraction L1 is not further purified since MTBE as solvent needs not to be pure. So L1 can be recycled directly to the extractor E, a part of it is used as reflux for C-1. In column C-2 a mixture of water and MTBE has been separated into pure water and MTBE – water azeotrope. Therefore, L2, the water-rich phase from the settler, can also be fed into column C-2.

The economy of the hybrid process depends on a careful optimization of operational and constructional parameters, besides the careful selection of the solvent. Recently, mixed integer nonlinear programming (MINLP) has been successfully introduced in optimization of such processes [93], [94]. MINLP can be used as a process synthesis tool. It is necessary to generate a so-called superstructure of the hybrid process which contains a variety of alternative flow sheets. Then MINLP is able to choose the best solution for given parameters and also from competitive unit operations like extractive distillation, processes with more than one solvent or processes with reextraction for solvent recovery.

Extractive Distillation. Another possibility to separate azeotropic mixtures is extractive distillation. A solvent with a much higher boiling point than the feed is fed at the top of a distillation column to entrain one component of the distillation feed that enters the column at the bottom (→ Distillation and Rectification, Chap. 6.5.). The combined system of liquid – liquid extraction and extractive distillation is applied in nearly all processes used to manufacture

very pure light aromatics. *N*-Formylmorpholine is a suitable solvent to separate the light aromatics benzene and toluene used as feedstock for the petrochemical industry [95–100]. Due to the selectivity of *N*-formylmorpholine (NFM), extremely high yields of very pure products are obtained.

Figure 48. Triangular diagram (A) and flow sheet (B) of a hybrid extraction – distillation process for separation of water and acetic acid with MTBE as solvent [93]
E = extraction; C-1, C-2 = distillation; S = settling; H = condenser

A simplified process flow scheme for *N*-formylmorpholine extraction is given in Figure 49. Feed enters the extractor at an appropriate point in the bottom half of the column. The exact location depends on the composition of the feed and can be optimized for each feedstock. Solvent enters at the top of the extractor at the selected temperature. Because NFM has a high solvent power, this must often be reduced by addition of water. In general, 4 – 10 % water is sufficient to ensure a low solubility of saturated hydrocarbons while still maintaining a high solubility of aromatics. The raffinate phase leaving the top of the extractor is saturated with solvent. Washing with water has proved to be a simple and effective means of recovering dissolved solvent. The water – solvent mixture from this washing operation is charged to the bottom of the main extractor to increase the water content of the solvent phase as discussed above.

The solvent – aromatics mixture from the bottom of the extractor still contains some alkanes. This stream is routed to an extractive distillation column. In the lower part of this column, saturated hydrocarbons are stripped off, which results in high-purity aromatics at the bottom. Because the volatility of alkanes in the presence of NFM is much higher than that of aromatics, the need for sharp separation is not very high. At the top of the extractive distillation column, some solvent is added. This solvent stream serves to wash back any aromatics evaporated at the feed point. The resulting top product, therefore, has a very low aromatic content and is very effective as a reflux in the bottom part of the extractor, washing out the heavier alkanes.

The bottom product of the extractive distillation column, consisting of solvent and very pure aromatics, is fed to a distillation column where the aromatics are evaporated along with water. The top product of this column is condensed and fed to a settler. The extracted aromatics are available as product or can be routed to a distillation train to separate the individual compounds. Some of the aromatics are returned to the top of the distillation column as reflux. In this way, any ascending solvent vapor is condensed and the top products are solvent-free. The water layer from the settler is used for raffinate washing. Sometimes, part of the water is used as reflux instead of extract. In this combination, ultimate use is made of the solvent characteristics in both the extraction and the extractive distillation steps.

5.3. Reactive Extraction

5.3.1. Introduction

If the solvent reacts with the extracted substance during the extraction, the whole process is called reactive extraction. This reaction is normally

Figure 49. Morpholine solvent process
a) Extractor; b) Washing; c) Extractive distillation column; d) Distillation column; e) Settler

used to alter the properties of inorganic cations that are to be extracted from an aqueous solution to make them soluble in the nonpolar organic solvent. The reaction mechanism can best be compared with a *cation exchange* process. The solvent acts like a liquid ion exchanging the ion to be extracted for protons.

Table 1. Commercial chelating extraction reagents

Name	Producer	Chemical composition
LIX 63	Henkel	5,8-diethyl-7-hydroxy-6-dodecanone oxime
LIX 64	Henkel	2-hydroxy-5-dodecylbenzophenone oxime
LIX 64N	Henkel	LIX 65N with added LIX 63 (promoter)
LIX 65N	Henkel	2-hydroxy-5-nonylbenzophenone oxime
LIX 70	Henkel	chlorinated LIX 65 N with added LIX 63 (promoter)
LIX 71	Henkel	mixture of LIX 64 N and LIX 70

P 5200	Acorga	one part P 50 with two parts nonylphenol
P 5300	Acorga	one part P 50 with three parts nonylphenol
P 5050	Acorga	two parts P 50 with one part tridecanol
Kelex 100	Sherex	substituted 8-hydroxyquinoline with 10 % isodecanol
Kelex 120	Sherex	similar to Kelex 100 but with 20 % isodecanol

The use of this process for extraction of anions is far less known but is of the same importance. The mechanism of this type of reaction proceeds most of the time through ion pair formation and can best be compared with an *anion exchange process*.

A third possible mechanism is the *solvating and/or chelating reaction*. In a reaction of this type, one or more molecules of water in the hydrate layer of the ions are replaced by the active solvent. The new complex will be insoluble in water but soluble in the solvent.

Generally, the formation of a complex is a slow reaction. Therefore, in many cases, it is not possible to use columns for this type of extraction. In many applications mixer – settler are used to make the extraction possible.

A reactive extraction will need a re-extraction to isolate the extracted substance from the solvent. The active solvents used in reactive extractions are water insoluble compounds. They are used undiluted or in solution in an inert solvent.

5.3.2. Extraction Mechanism of Different Types of Solvent

Classical Complexing and/or Chelating Agents. The active solvents are usually large, polyfunctional molecules. Most of them are designed to extract specific cations. Dioximes, hydroxyoximes, quinolines, β-diketones, etc., are rather expensive but widely used solvents to extract metal ions such as copper and nickel from the aqueous phase.

Metal complexes are formed in the water phase in a substance-specific pH range and extracted into an inert solvent. After extraction the metal ion is liberated from the complex by changing the pH, and re-extracted into the water phase. The complexing/chelating agents are designed such that they are chemically stable, nontoxic, and insoluble in water to minimize losses. The liquid ion exchange (LIX) [5] agents used in the production of copper are typical for this category.

Henkel, Hoechst, Shell, Sherex, and Acorga are the largest producers of complexing/chelating extractants (see Table 1).

Phosphoric, Sulfonic, and Carboxylic Acids. This class of products acts typically as cation exchangers in solution. The products have one or more protons that can be exchanged for metal ions.

Naphthenic acids

Versatic acids

Sulfonic acids

Phosphoric acids

Thiophosphoric acids

Phosphonic acids

The metal salts of these acids are soluble in most nonpolar solvents and, depending on the pH of the extraction and the pK_a of the acid, the cation will migrate to the organic phase or stay in the water phase. The dependence of the distributions coefficients on pH is shown in Figure 50.

The different curves give the variation of the distribution coefficient D in dependence of pH for different cations. These solvents are not specific for certain cations, but are very suitable to concentrate and recuperate trace elements from effluent streams [109], [110].

The major producers of this type of compounds are Bayer, Hoechst, Daihachi, Shell, and Albright & Wilson.

Ethers and Thioethers.

$$R_2O + HX \rightleftharpoons R_2OH^+ + X^-$$

$$R_2S + HX \rightleftharpoons R_2SH^+ + X^-$$

where HX stands for a strong acid, e.g., H_2SO_4 or HCl, and X is the anionic rest of the acid. Most metal ions that are capable of forming anionic complexes are extractable with ethers and thioethers. Fe, Au, In, Ga, etc. can be extracted with these solvents from an aqueous HCl solution (HCl concentration > 6 M) and re-extracted from the organic phase with water. Most of these anionic complexes form strong acids which protonate with the ether group to form oxonium (thionium) salts. These salts, however, are soluble in ether or thioether. It is also possible to extract Cl^- from water with $(R_2O)_2 \cdot H_2SO_4$, the sulfate ion being replaced by the chloride. This type of solvent is normally used in undiluted form [106].

Ketones extract the same anionic complexes as ethers, but in most cases at lower acid concentration. Complexes with weaker acids can also be extracted. Methyl isobutyl ketone and cyclohexanone are industrially used in the separation of Nb – Ta as F^- complexes [112] (→ Niobium and Niobium Compounds, Chap. 4.3.1.) and in the separation of Zr – Hf as CNS^- complexes (→ Zirconium and Zirconium Compounds, Chap. 1.4.2.) [116]. The solvents are used in undiluted form. A great disadvantage of this and of the former type of solvents is that they are not completely insoluble in water. A distillation is needed to remove the dissolved solvent from the water phase.

Trialkylphosphine oxides, Trialkylphosphinates, -phosphonates, and -phosphates.

$$R_3PO + HX \rightleftharpoons R_3POH^+ + X^-$$

$$ROR_2PO + HX \rightleftharpoons ROR_2POH^+ + X^-$$

$$(RO)_2RPO + HX \rightleftharpoons (RO)_2RPOH^+ + X^-$$

$$(RO)_3PO + HX \rightleftharpoons (RO)_3POH_+ + X^-$$

Figure 50. Plots of log D vs. pH for extraction of metals

With this type of extractants most metals from group 3 to group 8 can be extracted, even if only weak complexes are formed with the solvent. It is for example possible to extract $TiOSO_4$ [114] from a sulfuric acid solution with dibutyl butylphosphonate (DBBP) as the solvated complex $2\,DBBP \cdot TiOSO_4 \cdot H_2SO_4 \cdot 5\,H_2O$. These organophosphorus solvents are, due to their outstanding chemical stability and good physical properties, most widely used in reactive extraction [107], [108].

Free acids can also be extracted, the basicity of the solvents decreases from phosphine oxide to trialkylphosphate. The distribution coefficients are rather small so that large volumes of solvent are needed in an extraction process [104], [105], [111]. These extractants are used as such or diluted in an inert solvent (petroleum fraction) with or without modifier. The distribution coefficients in metal extraction are usually very high and depend on the acid concentration. The products are rather expensive.

Bayer, Hoechst, Daihachi, Shell, and Albright & Wilson are the major producers.

Trialkylsulfonium (Selenium, Tellurium), Tetraalkylammonium, and Tetraalkylphosphonium (Arsonium, Stibonium) Salts.

$$[R_4N^+A^-]_{Solvent} + [B^-]_{Raffinate} \rightleftharpoons [R_4N^+B^-]_{Solvent} + [A^-]_{Raffinate}$$

These onium compounds form ions both in acidic and basic medium. The mechanism of extraction is practically always anion exchange [106]. The onium compounds are regenerated in the same way as anion exchanger resins by re-extraction with a base. These solvents are used in the production of Cr, V, Re, Tc, Mo, and W as a solution in a petroleum fraction.

Producers are Henkel, Sherex, Hoechst, and BASF.

Amine and Phosphine Salts.

$$R_3N + HX \longrightarrow R_3NH^+ + X^-$$

$$R_3P + HX \longrightarrow R_3PH^+ + X^-$$

Primary, secondary, and tertiary amines must be protonated, thus converted to the ionic form before they can be used as an ion exchanger. Thus acids can be extracted with free amines, metals have to be transformed to the corresponding acids: vanadium can be extracted as HVO_3, chromium as $H_2Cr_2O_7$, and manganese as $HMnO_4$. Most used are the tertiary amines because they are chemically inert to most reagents.

In the system trilaurylamine – citric acid a reversible extraction can be set up, due to the difference in distribution coefficient at different temperatures. At low temperature (20 °C), the distribution coefficient solvent/raffinate is > 10. At high temperature (130 °C), the coefficient for the same system is < 1. Thus, the acid can be extracted from water at low temperature and re-extracted with water at high temperature. Much less accounted for is the fact that these amines have very different distribution coefficients for different anions.

$$[R_3NH^+A^-]_{Solvent} + [B^-]_{Raffinate} \rightleftharpoons [R_3NH^+B^-]_{Solvent} + [A^-]_{Raffinate}$$

For trioctylamine in an aromatic solvent the order of extractability is

$$I^- \gg Br^- > NO_3^- > Cl^- \gg F^- > S_2O_3^{2-} > PO_4^{3-} > SO_4^{2-}$$

This series is dependent on the type of amine, the diluent, and the temperature and must be determined for any given system [5]. This series can be enlarged for organic compounds, capable of forming ion pairs with the amine. Phenols and substituted phenols can be extracted with better distribution coefficients than chlorides. In this series thiophenols and some mercaptans are situated between bromide and nitrate and all sulfonic acids are better extracted than phosphate. This makes the sulfate salts of amines a very good choice for new extraction systems.

$(R_3N)_2 \cdot H_2SO_4$ (R = octyl) is capable of extracting Cl^- and/or NO_3^- [113] from a mixture of both anions with SO_4^{2-}. The value of the distribution coefficient of the anions is surprisingly high.

$$D_{Cl}/D_{SO_4} \approx 100$$

$$D_{NO_3}/D_{SO_4} \approx 400$$

A disadvantage of these solvents is the fact that per mole amine one mole of salt is formed after regeneration. However, most of the time, the anions to be removed are present in the solution only as trace impurities, so that this drawback is not significant. Another disadvantage of amines is the poor solubility of ammonium salts in aliphatic hydrocarbons. To avoid third phase formation, the use of aromatic solvents (smell) or aliphatics with modifiers is necessary. Amines can also act as solvating agents in an acid medium. Iron, zinc, and uranium salts can be extracted in this way [106].

5.3.3. Uses

1) A bleed from a $(NH_4)_2SO_4$ crystallization unit in a caprolactam plant contains 40 % $(NH_4)_2SO_4$, 10 % NO_3^-, 50 ppm Cl^- and 3 – 4 % organic sulfonic acids. The solution is extracted by trioctylammonium sulfate, the added amount is stoichiometric to $[NO_3^-] + [Cl^-] +$ [sulfonic acid]. In three stages > 99 % of the nitrate, 90 % of the chloride, and 85 % of the sulfonic acids are extracted by the trioctylamine in solution (40 %) in Shellsol AB (aromatic hydrocarbon). The raffinate is returned to the crystallization plant for $(NH_4)_2SO_4$recovery. The re-extract contains 35 % of nitrate, 0.016 % of chloride, the sulfonic acids, and only 0.1 % of sulfate and is treated separately. Compared with a conventional stripping, the use of chemicals in this system is strongly reduced. 80 % less NaOH is consumed because the base is only used to liberate the amine and not to neutralize the NH_3 from $(NH_4)_2SO_4$ [113].
2) Traces of phenol (20 – 200 ppm) and bisphenol (20 – 100 ppm) can be extracted from the wastewater of a polycarbonate plant to values < 1 ppm, thus avoiding biological treatment of the water. The re-extract containing sodium phenolate and bisphenolate (300 – 500 times more concentrated) can be returned to the polycarbonate plant. The solvent used is 5 % trioctylamine in Shellsol AB [117].
3) From a plant for the production of vulcanization accelerators 2-mercaptobenzothiazol (100 – 300 ppm) and its oxidation products are completely extracted in two stages and re-extracted as a 20 – 30 % solution. This concentrated waste can be easily removed. The solvent is 20 % trioctylamine in Shellsol AB [113].
4) Bromide ions can be extracted selectively from sea water (concentration in the Dead Sea ≈ 4 %) with amine hydrochlorides and concentrated in a re-extraction step, thus avoiding the energetically unfavorable stripping of sea water. The extraction can be carried out with various types of amines as HCl or H_2SO_4 salt [106].
5) Mg^{2+} can be removed from a saturated solution of $(NH_4)_2SO_4$ by extraction with the ammonium salt of diethylhexyl phosphonic acid (DEHPA) at pH > 5. It can be recovered by lowering the pH to < 3 [115].
6) Traces of uranium are extracted from phosphate ores. The uranium content in these ores is only 30 – 300 ppm. The reserves of those ores are so huge that the quantity of uranium from phosphates many times exceeds that of uranium found in other uranium ores.
7) Lanthanides and actinides have only recently become available in higher quantity and high purity. This was enabled by the development of the extraction technology (→ Rare Earth Elements).

8) Worldwide about 40 % of the copper is produced by reactive extraction. The plants are an order of magnitude larger then any other type of solvent extraction presently in operation (→ Copper, Chap. 5.8.). With an aqueous feed of 200 – 3000 m^3/h a whole new technology had to be developed. Copper can be extracted after acid or ammoniacal leaching. The aqueous stripping phase is used directly in the electrowinning of copper. To avoid the build-up of impurities in the electrolysis of copper, Fe, Zn, and other metals are removed from this phase by extraction with other solvents [5], [102], [111].
9) More than 90 % of the world production of cobalt is performed by reactive extraction. Separation of Co and Ni can be achieved from alkaline, neutral, or from acidic media. Most of the impurities (Sn, Bi, Fe, Pb, Cu, Cd, and Zn) have to be removed from the solution by precipitation or extraction. From a medium concentrated aqueous chloride solution (100 – 200 g/L), Co can be extracted by amines together with only traces of Ni. After scrubbing with 4 – 5 M HCl, most of the Ni is removed from the solvent. The cobalt is stripped by water.
   From neutral or weakly acidic media (pH 4.8 – 5.5) Co can be extracted by the Na^+ or NH_4^+ salt of di-2-ethylhexylphosphoric acid (D2EHPA) (to avoid acidification of the aqueous solution). Some Ni is co-extracted and is removed by scrubbing with a Co solution thus replacing any extracted Ni by Co. Co is finally stripped by HCl, H_2SO_4, or HNO_3 depending on the use.
   The use of monooctyl octylphosphonic acid (MOOP) to replace D2EHPA [101] permits the same separation, but at lower pH and with enhanced distribution constants for Co.
   In alkaline solution Co and Ni can be extracted by LIX agents from ammoniacal solution. Prior to the extraction, cobalt is oxidized to the Co^{3+} state. Nickel is stripped first with dilute acid, Co remaining in the solvent. Cobalt is then reduced to the Co^{2+} state and stripped with diluted acid [5], [102], [104], [105].

All these examples are used in industry or in pilot plants. Elaborate process and flow control are essential to use this technology in a economical and meaningful way.

5.3.4. Setting up an Extraction System

A solution R contains three components: acid, metal A and metal B. Both metals and the acid are extractable with a solvent S and metal A is the desired component that is to be obtained in acid solution. The procedure to set up a new extraction system with these data is typical for any reactive extraction system [114], [118].

The distribution coefficients are to be measured at different acid concentrations at a temperature suitable for the extraction. A typical measurement curve is shown in Figure 51.

Figure 51. Distribution coefficient in dependence on acid concentration

The diagram shows a poor, practically constant distribution coefficient *D* for the acid and an increasing one for both metals A and B at increasing acid concentration.

This means that the acid extraction is in fact a normal physical extraction and that both metals form solvation complexes. At any acid concentration, all three components are extracted together. The extraction coefficients *E* are related in the same way as are the distribution coefficients,

$$E = D \cdot S / R.$$

To extract metal A completely and in a reasonable number of steps extraction has to be carried out in zone 4 of Figure 51, the *extraction zone*. At the same time, metal B and the acid are only partially extracted into the solvent. The number of steps can be calculated with the Kremser formula. The Kremser formula calculates the efficiency *Z* in the extraction

$$Z = \left(E^{n+1} - E\right) / \left(E^{n+1} - 1\right)$$

over n stages. For this equation the number of stages can easily be calculated

$$n = \log \{[1/(1-Z)\cdot(1-1/E)] + 1/E\} / \log E$$

To remove metal B from the solvent the solvent has to be washed with water or acid in such a way that most of metal A stays in the solvent, while metal B is washed out as completely as possible. This is done in zone 3 of Figure 51, the *scrubbing zone.* The amount of water to be used is given again by the distribution coefficients of both acid and metal B. If too much acid is removed, metal A will also be washed out. Therefore it is more adequate to use an acid solution. The concentration of the dilute acid should be such that the acid solution can only take up the amount of acid to be removed from the solvent. By scrubbing with pure water only a limited amount of scrubbing fluid can be used because of the low distribution coefficient of the acid. By adding a calculated amount of acid the amount of scrubbing fluid can be increased and more component B can be removed without removing component A. The raffinate, leaving the scrubbing zone contains too much of metal A to be discarded and is sent back to one of the steps in the extraction. The number of steps can again be calculated with the Kremser formula.

In zone 2 of Figure 51, the *stripping zone*, metal A is washed out of the solvent with water or a dilute acid solution. The amount of water is chosen such as to obtain the desired concentration of metal A in the re-extract. With the given distribution coefficient, it is not possible to remove metal A completely form the solvent. At any acid concentration, traces of metal A will remain in the solvent.

In zone 1 of Figure 51, the *washing zone*, the acid and the rest of metal A are washed out of the solvent. After this step, the solvent is completely regenerated and can be reused.

General Flow Sheet. Figure 52 shows a general flow sheet of a reactive extraction system.

Solvent Make-Up. Due to the poor distribution coefficient of the acid several extraction steps are needed to load the solvent with sufficient acid to make extraction of the metals possible. In the given example the acid comes from the initial solution. To avoid losses of metal A, the solvent must be completely free of A. At the low acid concentration in the first steps of the solvent make-up any metal A present in the solvent will be re-extracted in the raffinate.

Reactive Extraction. If sufficient acid is present in the solvent, both metals will be extracted from the feed solution. To limit the number of steps in the extraction, concentrated acid is added. The high concentration is necessary for the metal extraction and in the solvent make-up.

Solvent Scrubbing. To make sure that most of metal B is washed out from the solvent, the acid solution containing metal A and acid from the solvent washing step is used, so that we stay in the extraction zone for metal A. The second component, with a lower distribution coefficient, is already in its stripping zone and will be washed out of the solvent. To avoid losses, this stream is sent back to one of the steps in the extraction.

Solvent Stripping. After scrubbing, the solvent contains only metal A and acid. Using water or a dilute acid solution, the purified metal A can now be re-extracted into a water phase.

Solvent Washing. The solvent must be completely regenerated before it can be recycled to the solvent make-up. This is done by adding some supplementary washing steps to the system. The amount of water is chosen according to the requirements in the scrubber and the number of steps is calculated as a function of that amount.

5.3.5. Diluents and Modifiers

Diluents are used to reduce the solvent viscosity, improve phase separation, and most of all, when properly chosen, to reduce the loss of solvent. The solubility of tri-*n*-butyl phosphate (TBP, one of the most frequently used extractants) in pure water is 420 mg/L at room temperature; a 50 % dilution of TBP in *n*-hexane lowers this solubility to 175 mg/L. The choice of diluent is very important. Higher amines are completely soluble in aliphatic diluents. Their salts, however, are only slightly soluble in the same solvents. Therefore it is essential to test the solutions in all steps of the process. If third-phase formation occurs in one of the steps, the diluent must be changed or a *modifier* is to be added. These modifiers are normally long chain alcohols, monoesters of polyhydric alcohols, or phosphate

Figure 52. General flow sheet of a reactive extraction system

esters. These modifiers may considerably influence the kinetics of the extraction. Especially in the extraction of copper the choice of modifier is very important. The different types of solvent are sold mixed with a suitable modifier which greatly enhances the extraction performance of the solvent.

1. Introduction

Theodor Voeste and Klaus Weber

Liquid – solid extraction, also called *leaching* or *lixiviation*, is the process of totally or partially dissolving a solid in a suitable solvent. Lixiviation is derived from the Latin word *lixivius* which means made of lye.

Liquid – solid extraction covers a variety of processes such as the extraction of oilseeds, bone, fuller's earth, and catalysts. Further examples are the production of sugar from beet and sugar cane and the extraction of bitumen from oil-impregnated rock or sand. Laundries, dry-cleaning, and the making of coffee from ground coffee beans are everyday examples of automated leaching processes.

Extraction is often accompanied by a chemical reaction which converts the extract into soluble form; examples of chemical leaching are the hydrolysis of wood, cellulose digestion, and many leaching and decomposition processes used in metallurgy and the pigment industries.

The first chapter of this article describes extraction without chemical reactions which depends solely on the solubility or miscibility of the extract in the solvent. Oilseed extraction is primarily described because its characteristics and objectives are typical for the physical processes and equipment used in other applications.

Chemical leaching in hydrometallurgy is discussed in the second chapter. The third chapter deals with supercritical-fluid extraction, also called gas extraction which is a relatively modern technology. Here extraction is achieved with a gas or gaseous mixture under near-critical conditions (pressure and temperature). Near the critical point, the differences between the liquid and gas phases disappear and extraction occurs via the resulting fluid phase. This separation process bears some resemblance to distillation and is sometimes referred to as destraction.

For detailed information on specific extraction processes, see ⟶ Coffee, ⟶ Coffee – Brewed and Instant (Soluble) Coffee; ⟶ Fats and Fatty Oils – Extraction ; ⟶ Sugar; ⟶ Tar Sands.

2. Extraction without Chemical Reaction

Theodor Voeste and Klaus Weber

2.1. General Comments

Definitions. Some of the technical terms used in this chapter are listed below together with their meanings:

Feed material	(prepared) raw material which is to be extracted
Extract	substance which is to be separated from the feed material
Solvent	medium used to carry out the extraction
Miscella	the conventional expression in the oilseed crushing industry for the extract solution
Degree of extraction	(extract in feed material – extract in extraction residue)/extract in feed material

A cost-effective extraction process must fulfill the following requirements:

1. The feed material must be prepared in such a way that the solvent can dissolve the extract quickly. This is achieved by crushing, grinding, or flaking.
2. Only the desired extract should be dissolved and leached out. This is governed by the solvent selectivity and the temperature.
3. The extract should be recovered at the highest possible concentration. Therefore, plants in which the solid and liquid pass countercurrently to one another are widely used.
4. Economic separation of the solvent from the extract solution and in many cases, from the extraction residue must be possible (e.g., by means of distillation or solvent extraction).

The complete extraction process usually includes the following additional stages: preparation of the feed material, as well as separation and recovery of the solvent from both the extract and the extraction residue (see Fig. 1).

Figure 1. Schematic diagram of liquid – solid extraction

Comparison of Extraction with Pressing. Many substances can be obtained by liquid – solid extraction (e.g., quinine, coffee, tea, as well as drugs, and alkaloids), but vegetable oils and some other substances can also be produced by mechanical pressing (expelling). If the feed material has a high oil content, mechanical pressing is the more economic method. However, pressing gives a residual oil content of approx. 5 wt % at best, and is accompanied by undesirable heating of the solid expeller cake, and possible deterioration of the oil. For this reason, prepressing is normally used in the oil industry to obtain a residual oil content of 15 – 20 wt %: the remaining oil is obtained by extraction with light hydrocarbons. The mechanical wear in the presses and the ever-increasing cost of routine maintenance certainly favor total extraction, especially as the capital cost of pressing increases approximately in proportion to the throughput whereas the relative capital cost of leaching decreases.

Oil is obtained from oilseeds with relatively low oil content (e.g., soybeans) solely by extraction. In modern countercurrent plants, liquid – solid extraction can achieve residual oil contents of 0.3 wt %. Much higher throughputs can be achieved with one and the same plant and the same expenditure if residual oil contents of 0.6 – 1 wt % are acceptable. Most industrial plants now operate in this range, the more so because such oils are of improved quality and contain less unwanted contaminants.

The dependence of the degree of extraction on the throughput is typical of all leaching plants. A very high degree of technical effort is required to remove the final residues of extract; this can easily be demonstrated theoretically [1].

Sometimes extraction can yield different extracts depending on the conditions used. In the case of rice bran, for example, an oil is extracted at low temperature and a wax at high temperature. A polar solvent can be used to extract the water from

bones in a cold stage and the bone fat in a hot extraction step [2], [3].

2.2. Technical Principles and Process Design

Structure of the Feed Material. The extract may be present in the feed material in solid or liquid form. It may, like the oil in oilseeds, be enclosed in cells, or, as in coffee, be attached to the carrier material as a fine dispersion.

The feed material is not homogeneous but porous and contains many capillaries. At the start of extraction, the solvent penetrates into the material through the capillaries and dissolves the extract forming a highly concentrated solution. During the extraction process, diffusion produces virtual equalization of the concentrations of the extract solution in the feed material and of the extract solution surrounding the solid. After completion of the process, a certain quantity of solvent is retained by the residue as a result of adhesive forces. This adherent solvent contains a quantity of extract which remains in the extraction residue after the solvent has been expelled. In practice there is no such thing as total extraction.

Extraction Rate. Three main theories have been proposed to account for the factors governing the rate of extraction; to some extent, these can be substantiated experimentally and described by mathematical expressions. The diffusion theory [4] implies that the extraction rate depends primarily on the rate of diffusion. The soaking theory [5], [6] assumes that the extraction rate is determined not only by the rate of diffusion but also by the rate of dissolution of the extract in the solvent. A third theory interprets the extraction rate as a function of the flow rate of the extract solution in the capillaries [7].

The following requirements for a high extraction rate can be deduced from these theories:

1. The extraction should be carried out at the highest possible temperature because the viscosity and solubility of many extracts are temperature-dependent.
2. The capillary paths must be short so that the distance over which diffusion occurs is as short as possible. Short capillary paths are achieved in materials which are extracted using the displacement system (see Section Extraction Processes and Typical Equipment) by fine grinding of the feed material. If the extraction is carried out on the percolation principle, the feed material must be prepared in such a way that the solvent can percolate freely. For this reason, materials such as oilseeds are rolled to thin flakes to produce a feed material with short capillary paths in one direction and good percolation properties (Fig. 2) [8]. Flaking should disrupt the oil-containing cells to allow direct contact between the solvent and the extract. Solids such as fish meal, which are very finely divided, have short capillary paths, but the rate of percolation is so low that pelletizing must be used to produce a granular material with adequate percolation properties.
3. The percolation rate must be as high as possible in order to wash away the extract solution that has diffused to the surface of the solid particle. This ensures that a high concentration gradient always exists between the extract solution in the capillaries and the extract solution surrounding the particle. In the case of powdered solids, concentration equilibrium between the concentrated extract solution at the particle surface and the bulk extract solution can be attained more rapidly by stirring.
4. To achieve good efficiency at each stage in multistage extraction, only a small amount of solvent should be retained by the feed material. This is achieved industrially by using drainage zones. Pressing or centrifuging is often not justifiable because each of these techniques requires a high degree of technical effort.

Figure 2. Extraction of soybean flakes of differing thickness during percolation with hexane

Flake thickness, mm: a) 0.22; b) 0.35; c) 0.43; d) 0.55

Number of Theoretical Extraction Stages. In order to design and dimension equipment for extraction and distillation of the solvent from the extract solution and the extraction residue, the solvent requirements and the number of theoretical extraction stages must be known. In this context—as in distillation—the number of theoretical extraction stages denotes the number of theoretical solvent equilibria that are required to achieve a given final state from a specified initial state. They are either calculated by drawing up the mass balances for the individual stages or determined graphically [1], [9]. The extract contents of the residue and the solution are specified. The composition of the feed material and the quantity of solvent taken up by it are measured experimentally as a function of the concentration.

The following numerical example of a simplified method for calculating the number of theoretical extraction stages is taken from [1]. This publication also contains the derivation of the equation for the operating curve used in the calculation.

The required number of theoretical stages is to be determined for an oilseed extraction with a light hydrocarbon such as hexane.

Initial oil content of the oilseed	20.0	wt %
Permissible residual oil content in the meal	0.5	wt %
Required oil content of the micella (extract solution)	30.0	wt %

Table 1 shows the results of the experimental determination of the amount of adherent solvent l_n and its content of extract e_n at full equilibrium.

Table 1. Experimental results of an oilseed extraction used to determine the number of theoretical extraction stages for 1000 g of carrier material

Oil concentration of the adherent solution x_n, wt %	Amount of adherent solution l_n, g	Amount of adherent extract e_n, g
50	874	437
30	600	180
20	530	106
10	480	48
0	450	0

The following equation is used to establish the operating curve:

$$y_n = \frac{(E_{end} - e_a) + e_n}{(L_{end} - l_a) + l_n}$$

where the symbols and subscripts in the equation have the following meanings:

e	amount of extract in the adherent solution
E	amount of extract in the free solution
l	amount of adherent solution
L	amount of free solution
$x = e/l$	extract concentration in the adherent solution
$y = E/L$	extract concentration in the free solution
a	material entering the system
end	material leaving the system
n	an arbitrary intermediate stage

The individual parameters in the equation are calculated as follows:

e_a: If the oil content of the seed is 20 %, then 1000 g of carrier material (as the reference quantity) corresponds to an oil content of 250 g, i.e., e_a= 250 g

E_{end}: For oil extraction giving meal with a residual oil content of 0.5 %, i.e., 5 g of oil per 995 g (≈ 1000 g) of carrier

$E_{end} = e_a - e_{end} = 250 - 5 = 245$ g

L_{end}: Since the required oil content of the miscella is 30 %, 245 g of oil corresponds to 30 % of the final amount of solution L_{end}, thus

$L_{end} = \frac{100}{30} \times 245 = 817\,\mathrm{g}$

l_a: As the fresh oilseed does not contain any solvent, the oil is present as a 100 % solution, i.e., $l_a = e_a$= 250 g

The equation then becomes

$$y_n = \frac{(245 - 250) + e_n}{(817 - 250) + l_n} = \frac{(-5) + e_n}{(567) + l_n}$$

Substitution of the experimental values for e_n and l_n listed in Table 1 give the values for y_n (Table 2).

Table 2. Calculation of the operating curve from the experimental results given in Table 1

x_n, wt %	e_n, g	l_n, g	y_n, wt %
0	0	450	–0.5
10	48	480	4.1
20	106	530	9.2
30	180	600	15

50 437 847 30

The points x_n and y_n are plotted in a coordinate system and then joined together to produce the operating curve. The equilibrium curve is the 45° line where $y = x$ (Fig. 3).

Figure 3. Graphical determination of the number of theoretical extraction stages

The steps between $x_{a,\ total}$= 50 % (corresponding to y = 30 %) and y = 0 % (corresponding to x_{end}= 1.1 %) produce five points, i.e., theoretical stages, on the equilibrium curve.

In this method, the extract is assumed to be completely dissolved in the solvent which means that extraction is not limited by diffusion. This is usually the case in industrial oil extraction where residence times are also determined by charging, discharging, and drainage. Thus, the number of theoretical extraction stages is virtually the same as the number of extraction stages required in practice. If dissolution equilibrium is not established quickly enough or is not achieved at all, the time dependence of the extraction rate must be determined experimentally and incorporated in the calculation [10].

Diffusional limitation in cellular structures is discussed in detail in [11-13].

Solvent Requirements. An “ideal” solvent must satisfy the following requirements:

1. High, selective dissolving capacity: only the required extract and no other constituents of the feed material are dissolved
2. Low specific heat, relative density, and heat of vaporization
3. Nonflammable, no formation of explosive mixtures with air
4. Nontoxic
5. Noncorrosive action on the extraction equipment
6. Good ability to penetrate the feed material, easy and complete removal from the extract and extraction residue without affecting their odor or taste
7. Chemically defined, homogeneous, and stable; constant boiling point which is not too high

No solvent fulfills all of these conditions, and the optimum solvent must be found for each extraction process. The most important solvents are: hydrocarbons (extraction naphtha), benzene, carbon disulfide, diethyl ether, acetone, chlorinated hydrocarbons, 2-propanol, ethanol, and water. Special effects can be achieved with mixtures of different solvents.

2.3. Extraction Processes and Typical Equipment

2.3.1. *Batch Extraction*

Batch extraction is based on the principle of displacement or enrichment.

Displacement Method. The displacement method is the oldest and simplest method of extraction. A given quantity of fresh solvent is added to the feed material. After thorough mixing, the extraction residue is allowed to settle and the extract solution is drawn off. If the liquid and solid phases cannot be separated by sedimentation, extraction pressing or centrifugation can be employed. The procedure is repeated until the required degree of extraction has been achieved. This system in which successive batches are treated with pure solvents is known as *multiple or cross-flow extraction.*

The disadvantage of this method is that, as the number of extraction steps increases, the concentration of the extract solution continually decreases and recovery of the solvent becomes more expensive.

The cross-flow method must, however, be used when a large concentration difference is required or when the mechanical flow properties of the feed material (slurry or powder) do not permit the use of any other method of processing. In principle, cross-flow extraction can also be performed continuously.

Enrichment Method. If the feed material has the required percolation characteristics, several extractors can be connected to form a battery. The solvent is then passed countercurrently through the extraction system. This mode of operation is called *counterflow battery extraction* or *enrichment process* (Fig. 4)

Figure 4. Schematic drawing of a battery extraction plant

a) Filling; b) Emptying; c) Separation of solvent and extraction residue; d) Drive

The solvent flows into the extractor containing the almost fully extracted material, and becomes increasingly enriched with extract as it flows through the following stages. It is withdrawn in a highly concentrated state from the extractor that contains the untreated material.

Investment cost and utilities consumption are lower for the enrichment process than for the displacement process.

Extractors. Batch (pot) extractors and rotating extractors are used in batch extraction. They serve both for the actual extraction process and for distillation of the solvent from the extraction residue.

Batch extractors generally comprise an upright cylindrical steel vessel of 2 to 10 m^3 capacity (Fig. 5). In processing by the enrichment method, the feed material rests on a perforated tray fitted into the vessel. The tray is not required in displacement extraction. Filling and emptying take place through the top of the vessel by loading the feed material into perforated trays. Separate connections are provided for solvent, steam, and vapor. The solvent is distilled off by direct heating. Steam is introduced through a purpose-designed distributor pipe.

Figure 5. Pot extractor

a) Removable lid; b) Perforated tray; c) Steel vessel

Rotating extractors consist of a horizontal steel vessel which is supported on bearings at both ends so that it can rotate (Fig. 6). It is filled and emptied through connections in the shell. The connections for the solvent, steam, and vapor lead to or from the hollow axle, which allows admission and discharge of liquids and gas during rotation. The use of heating coils and a heated double-jacket permits distillation of the solvent by indirect heating; the heating coils also act as agitators. Direct steam can also be introduced through built-in steam pipes.

Figure 6. Rotating extractor with double jacket

a) Filling inlet for feed material; b) Drive

Batch extractors are simple and robust. Their disadvantages are their limited capacity and batchwise output of product. Periodic filling and emptying make high solvent losses almost unavoidable. Due to the batchwise mode of operation, the vapor produced during distillation of solvent from the residue can seldom be used for heating the distillation plant in which the solvent is separated from the extract.

2.3.2. *Continuous Extraction*

Continuous extractors operate primarily on the percolation system. The percolation method requires a feed material which is highly permeable to the solvent. This procedure has the advantage that the feed is undisturbed and is therefore exposed to little mechanical stress. Self-sfiltration takes place during extraction when the liquid passes through the material. The extract solution has a minimal content of fine material.

Many extractor designs are available, only a few characteristic types are described here. The first extractor operating on the percolation principle to have proved itself in practice is the Bollmann *bucket-elevator extractor* (Fig. 7).

Figure 7. Bollmann bucket-elevator extractor

The extractor comprises an airtight casing in which buckets are fixed to an endless circulating chain. The feed material is fed into the buckets by means of a filling device. The solvent (which is already enriched with extract) is sprayed onto the buckets as they move downward; it then flows through the individual buckets, and is drawn off at the bottom of the extractor in highly concentrated form. On the downward side, extraction is cocurrent and self-filtration occurs. On the upward side, fresh solvent is fed in and flows countercurrently through the feed material, leaching out the extract. This extract solution is collected in a separate chamber at the base and is fed as the extracting medium onto the downward-moving buckets. After one cycle the buckets are tipped up and the extraction residue is discharged.

Continuous countercurrent percolation extractors with a capacity of up to 8000 t/d are widely used in modern large-scale plants to process bulk materials such as oilseeds. These types of extractor are also used for feed materials such as tea and drugs, which are processed in quantities of a few tonnes per day. The feed material is conveyed through the extractor by translation or rotation.

The material to be processed is fed continuously into the individual chambers (as in a box conveyor). In the extractor shown in Figure 8, the boxes move from right to left. Solvent or extract solution of differing concentrations is sprayed on in several stages. The liquid flow (from left to right in Fig. 8) is countercurrent to the material flow. Fresh solvent is fed in just before the feed material outlet; it passes through the material, is collected in a trough, and then pumped to the next extraction stage. This process is repeated in the subsequent stages and the solvent becomes increasingly enriched with extract. The highly

concentrated extract solution is withdrawn from the collecting trough of the final stage.

Figure 8. Schematic diagram of a continuous extractor

Higher liquid loads and, in many cases improved extraction for a given quantity of pure solvent, can be obtained if the extract solution from a given extraction stage is not passed immediately to the next stage but is recycled within the same stage. The associated collecting trough is then filled with extract solution. The amount of liquid that overflows into the next collecting trough corresponds to the inflow of extract solution from the previous collecting trough and the relevant extraction stage. In extractors operating on this principle, the height of the partitions between the collecting troughs decreases in the flow direction of the extract solution. Thus, the flow of extract solution is clearly defined and the liquid always overflows to the stage with the next highest concentration. This system is often used only in the first part of the extraction process, final leaching being a countercurrent process.

Figure 9 shows a *rotation extractor* or *carousel extractor* as supplied by Harburg-Freudenberger Maschinenbau GmbH. A rotor with sector-shaped cells rotates in an airtight housing over a fixed, slotted base. A sector of the base is open. The feed material is introduced continuously with a filling screw and extracted countercurrently. The extraction process is completed after a single revolution. The extraction residue is discharged through the open segment of the slotted base [14], [15].

Figure 9. Harburg-Freudenberger carousel extractor

The *De Smet Reflex extractor* operate in a similar manner to the carousel extractor.

The *Lurgi sliding-cell extractor* is shown in Figure 10. An endless belt composed of U-shaped cells runs on roller tracks and pushes the oilseed over stationary screen plates. The feed material is introduced evenly into the cells of the upper belt by a filling device. After approximately half the extraction time has elapsed, the feed is then dumped onto the lower belt. When extraction is complete, the material is passed through a drainage zone and discharged. The solvent passes through the feed material countercurrently to the direction of the belt and becomes enriched with extract; it finally leaves the extractor after a material filter stage.

Figure 10. Lurgi sliding-cell extractor

In the *De Smet LM extractor* (Fig. 11), the feed material is conveyed on a perforated belt and the height of the material bed is regulated by an adjustable slide. The extraction residue is discharged through a discharge gate.

Figure 11. De Smet LM extractor system

The *Crown Iron extractor* is based on the principle of a loop-trough chain conveyor (Fig. 12). It has one cocurrent extraction stage and two countercurrent extraction zones comprising several countercurrent stages.

Figure 12. Crown Iron loop-trough chain conveyor extractor

Continuous processes have a series of important advantages over batch processes. Large quantities of feed material can be processed in equipment of relatively small dimensions and compact design. High concentration of the extract solution is achieved with a low residual content of extract in the extraction residue; this allows a considerable reduction of solvent usage. The extraction times are shorter than those of batch methods and this has a beneficial effect on the quality of the end products. Economic, quantitative solvent recovery from the extraction residue and the extract solution constitutes an important part of liquid – solid extraction but is discussed elsewhere (⟶ Evaporation; ⟶ Distillation and Rectification – Energy Economization in Rectification).

[Top of Page]

3. Chemical Leaching in Hydrometallurgy

Brent Hiskey

History. PLINY described the extraction of salt from wood ash by the solvent action of brine [16].

AGRICOLA in his *De Re Metallica* (1556) indicates that the separation of silver and gold with nitric acid was well established by his time [17]. In 1661, a license was granted for the recovery of copper from mine waters at Rio Tinto in Spain; this probably involved the recirculation of leach solution through waste heaps [18].

An important development in liquid – solid extraction was the cyanidation of gold and silver ores. As early as 1783, aqueous solutions of potassium cyanide were known to exhibit a solvent action on gold [19]. However, it was not until the pioneering work of MACARTHUR and the FORREST brothers (1887, 1889) that cyanidation became a commercial process for treating gold ores [20]. Their contribution included two important advances: (1) the use of dilute cyanide solutions to selectively dissolve gold (stronger lixiviants, tend to dissolve numerous impurities), and (2) a simple method for recovering gold from the cyanide solutions by precipitation with zinc shavings.

3.1. Methods

Chemical leaching is customarily the first step in a hydrometallurgical sequence, but it may also be applied whenever the dissolution of a solid phase is desired. Figure 13 shows a general hydrometallurgical flow sheet. A broad range of raw materials can be treated: some are primary materials such as ores, mineral concentrates, and certain intermediate products (i.e., calcines, mattes); others are secondary materials such as scrap, sludge, and residues. Selective leaching can be used to concentrate a valuable constituent in the solid phase, as in the leaching of metallic copper from refinery anode slimes to concentrate gold and silver for subsequent recovery. Alternatively, leaching is often used to obtain an extract, called a pregnant leach solution, from which the valuable constituent may be recovered; the solid residue or gangue is discarded.

Figure 13. Major components of hydrometallurgical flow sheets

Leach solutions frequently require further processing to concentrate the desired components and remove impurities. A number of separation processes are used, including crystallization, adsorption, selective precipitation, cementation, ion exchange, and liquid – liquid extraction.

Product recovery is the final step in the hydrometallurgical sequence; the valuable component is then converted into a marketable product. Three techniques commonly employed for product recovery are electrolysis, gaseous reduction, and precipitation.

Leaching methods vary depending on the amenability of the solid to the specific leaching reaction and on the content or grade of the material. High-grade materials generally justify the added cost of prior comminution, sizing, and in some cases, concentration (i.e., flotation, gravity concentration, selective flocculation). Figure 14 illustrates different processing routes for leaching low-, intermediate-, and high-grade ores [21]. Ore is usually transported from mineral deposits for leaching; however, when the mineral chemistry and geologic conditions permit, it can be leached in situ. Low-grade ore, which does not justify any beneficiation, is typically leached on dumps and heaps. Intermediate-grade ores are often crushed or ground and sized for direct leaching in vats and agitated vessels. High-grade ore is normally of sufficient value to warrant the preparation of mineral concentrates. The concentrates may be suitable for leaching directly or may require pretreatment.

Figure 14. Processing routes for leaching various grades of ore

In situ leaching is performed on a mineral deposit in its natural or original geologic position. Liquid – solid contact may occur under either unsaturated or saturated flow conditions. Permeability enhancement may be required to improve solution flow through the rock mass and within rock pores and fractures. This can be accomplished by explosives, hydrofracturing, or chemical dissolution. To achieve high recoveries, in situ leaching often requires long leach cycles (usually years). Recovery

of copper from oxide and sulfide deposits, uranium from low-grade sandstone deposits, and soda ash from deep trona deposits are excellent examples of in situ leaching.

Heap and dump leaching are used to treat low-grade waste materials and some moderate- to high-grade ores not suitable for beneficiation. Leaching solutions are usually sprayed or sprinkled on the surface of the heap or dump and allowed to percolate through the material by gravity. The pregnant leach solution containing valuable dissolved components is collected and delivered to a metal-recovery circuit.

Figure 15 shows a heap-leaching system in which the run-of-mine (i.e., untreated) or crushed ore is placed on a specially prepared, impervious pad. Heap leaching has been used to recover copper and uranium, and has been widely applied to the treatment of low-grade gold and silver ores.

Figure 15. Schematic of a heap-leaching operation

a) Heap; b) Collection channel; c) Impervious leaching pad; d) Product recovery plant

Dump leaching is usually used to treat waste rock and, as such, does not justify crushing. Most dumps are deposited directly on the ground with little if any base preparation. Dump leaching is usually performed over a period of years, whereas heap leaching involves shorter periods (days to months). The dump leaching of low-grade copper waste from open-pit porphyry operations in the western United States is an important example of this technique [22].

Vat Leaching. In some cases, the valuable components desired may be finely dispersed in a nonporous solid matrix. Crushing and grinding may be required to permit adequate contact between the leaching solutions and the solid phase. The material can be leached in vats or tanks if the permeability of the bed permits percolation and circulation of the leaching solution. This system allows good liquid – solid contact, as well as washing and recovery of dissolved valuable components from the leaching residue. When compared with heap or dump leaching, overall recovery is usually higher, leach cycles are shorter (days), pregnant leach solution concentrations are higher, and soluble losses are lower. The vat leaching of copper oxide ores in Arizona is an important example of this technique [22].

Agitation Leaching. Fine grinding may be necessary to expose enclosed particles or to generate sufficient surface area to maximize extraction rates. Suspensions of fine particles can be leached in a tank or vessel by mechanical or air agitation in batch, continuous cocurrent, or continuous countercurrent circuits. Agitation (i.e., mixing) has two important effects: (1) the suspension and dispersion of solid particles in the solvent and (2) the promotion of efficient mass transfer between the solid and liquid phases. Gold and silver cyanidation is commonly accomplished by agitation leaching in staged circuits with residence times of 24 – 48 h. Other examples are the leaching of copper oxides or uranium ores, and the purification of molybdenite concentrates by dissolving impurities [23].

Pressure Leaching. In pressure or autoclave leaching, hydrometallurgical reactions are performed at high pressure above the normal boiling point of the leaching solvent. Other high-pressure systems use over-pressures of gaseous reactants to increase the solubility of the gas. Higher temperatures can increase both the solubility of dissolved species and their reaction rates. Autoclaves typically used for pressure leaching contain a mixer – impeller for agitation of the pulp, which is allowed to flow under pressure through the reactor. A classic example of pressure leaching is the Bayer process for the production of alumina (⟶ Aluminum Oxide – Bayer Process). Another important example is the pressure leaching of base-metal sulfides. Pressure oxidation is also applied to the treatment of refractory gold ores and concentrates [24], [25].

3.2. Principles

Selection of the leaching agent or *lixiviant* is very important and depends on the following factors:

1. Physicochemical nature of the solid to the extracted
2. Selectivity and stability of the leaching agent
3. Regeneration of the agent
4. Ability to recover the desired components from the leaching solution
5. Cost, toxicity, and availability of the agent

Water is the simplest leaching agent. A metal salt MX dissolves in water to yield its ions:

$$MX \rightleftharpoons M^+ + X^-$$

The thermodynamic equilibrium is established by the solubility product

$$K_{so} = [M^+][X^-]$$

Table 3 lists the solubility products and the total solubilities of selected metal sulfates [26-28].

Table 3. Solubility of metal sulfates in water

Metal sulfate	K_{so} *	Solubility, g/L **

$SrSO_4$	3.24×10^{-7}	0.14
$PbSO_4$	1.58×10^{-8}	0.045
$BaSO_4$	1.1×10^{-10}	0.00223
Ag_2SO_4	1.70×10^{-5}	5.7 (0 °C)
$CuSO_4$	4.43×10^{2}	225
K_2SO_4	0.0193	120
Na_2SO_4	0.645	338
Hg_2SO_4	7.41×10^{-7}	0.6
$CaSO_4$	9.12×10^{-6}	2.09 (0 °C)
$Al_2(SO_4)_3$	7.66×10^{16}	313 (0 °C)

* Calculated from data in [26] (25 °C).
** Solubility values at 25 °C except where otherwise indicated [28].

Some solids undergo hydrolysis when they dissolve in water, for example,

$$CaO + H_2O \rightarrow Ca(OH)_2$$

$$As_2O_3 + 3\,H_2O \rightarrow 2\,H_3AsO_3$$

In the presence of air or oxygen, water reacts with metal sulfides to produce soluble metal sulfates. The aqueous oxidation of the iron disulfide-containing mineral pyrite [1309-36-0] is an important example:

$$FeS_2 + 7/2\,O_2 + H_2O \rightarrow FeSO_4 + H_2SO_4$$

This reaction is useful in the dump leaching of low-grade, waste-containing copper sulfide [29]. It provides a source of sulfuric acid and dissolved iron, both necessary in the leaching of copper sulfide minerals (i.e., chalcopyrite, chalcocite, bornite): the iron(III) ions act as an oxidant and the sulfuric acid stabilizes the iron(III) ions in solution. Heat generated by the oxidation of sulfide promotes air convection and thus transport of oxygen through the rock mass. Bacteria use the oxygen to oxidize iron (II) ions to iron(III) ions, which constitute the primary oxidant.

To achieve the desired results in the leaching step, the leaching solution must be formulated to suit the problem at hand. This may involve adjusting the pH, setting a specific redox potential, or introducing complexing ligands.

Thermodynamics. Thermodynamic relationships of solids in contact with aqueous solutions of defined composition are best illustrated by redox potential (E_h) vs. pH, or Pourbaix, diagrams [30]. Although developed for metal corrosion equilibria, these diagrams are equally appropriate for geochemical and hydrometallurgical relationships.

Figure 16 represents the oxidation potential – pH diagram for the Cu – O_2– H_2O system. The broken lines indicate the limits of water stability; expressed as reduction reactions, they are

Figure 16. Redox potential – pH diagram showing stability regions for the copper – water system at 25 °C and 101.3 kPa

Concentration of dissolved copper species is 1×10^{-3} mol/L. Broken lines represent the limits of water stability.

$$2\,H^+ + 1/2\,O_2 + 2\,e^- \rightarrow H_2O(\text{upper limit})$$

$$2\,H^+ + 2\,e^- \rightarrow H_2(\text{lower limit})$$

Hydrogen is evolved below the lower line and oxygen above the upper line.

Figure 16 shows that copper oxide in its highest oxidation state may be soluble in a strong acid (to the left of the vertical line at pH 5.5, the stable phase is Cu^{2+} and not CuO)

$$CuO + 2\,H^+ \rightarrow Cu^{2+} + H_2O$$

or a strong base

$$CuO + 2\,OH^- \rightarrow CuO_2^{2-} + H_2O$$

Copper oxide in its lowest oxidation state may require oxidizing conditions for solution:

$$Cu_2O + 1/2\,O_2 + 4\,H^+ \rightleftharpoons 2\,Cu^{2+} + 2\,H_2O$$

However, some metal oxides in the highest oxidation state require reducing conditions to accomplish dissolution. An example of reductive leaching is the dissolving of manganese dioxide in sulfurous acid:

$$MnO_2 + 2\,H^+ + H_2SO_3 \rightleftharpoons Mn^{2+} + H_2SO_4 + H_2O$$

Manganese is reduced from the 4^+ to the 2^+ oxidation state in solution.

The role of a complexing agent is best illustrated with the gold – cyanide system. Figure 17 shows the redox potential – pH diagram for the Au – O_2– H_2O system. Metallic gold occupies a large area that includes the entire domain of water stability. The gold(I) ion (Au^+) does not appear on the diagram because it disproportionates spontaneously to the gold(III) ion and metallic gold

Figure 17. Redox potential – pH diagram showing stability regions for the gold – water system at 25 °C and 101.3 kPa

Concentration of dissolved gold species is 1×10^{-4} mol/L. Broken lines represent the limits of water stability.

$$3\,Au^+ \rightarrow Au^{3+} + 2\,Au$$

The gold(III) ion (Au^{3+}) and other oxidized forms of gold occur only at potentials above the upper stability limit of water. However, at these potentials, water is oxidized to oxygen, and the oxidized gold species is reduced simultaneously to the metallic state. Thus, metallic gold cannot be oxidized in strong acid or alkali in the absence of complexing ligands.

Gold dissolves readily in the presence of a complexing ligand and an oxidizing agent. Figure 18 represents the redox potential – pH diagram for the Au – CN – H_2O system. The presence of cyanide as a complexing agent results in a relatively large region of $Au(CN)_2^-$ stability, which makes cyanidation a practical process for leaching gold ores (⟶ Gold, Gold Alloys, and Gold Compounds).

Figure 18. Redox potential – pH diagram showing stability regions for the gold – cyanide – water system at 25 °C and 101.3 kPa

Concentration of dissolved gold species is 1×10^{-4} mol/L and of cyanide 1×10^{-3} mol/L. Broken lines represent the limits of water stability.

Reaction Kinetics. Reaction rate data are of practical importance for two reasons: (1) full-scale commercial leaching operations can be designed from kinetic data collected from bench-scale and pilot-plant tests, and (2) kinetic data can be used to predict processing under various conditions.

Liquid – solid extraction is a multistep, heterogeneous process that includes [31]:

1. diffusion of reactants to the particle surface,
2. adsorption,
3. surface chemical reaction,
4. desorption, and
5. diffusion of products to the bulk solution.

If a solid product layer surrounds an unconverted core, both the reactants and the soluble products must diffuse through the pores of this layer. The overall reaction rate is determined by the slowest step(s); in some cases, diffusion is rate-limiting.

Diffusion. Transport of a reactant to the solid – solution interface involves diffusion through a viscous boundary layer in the vicinity of the solid. Figure 19 depicts the concentration profile of the diffusion boundary layer for inward flux; the solid line represents the true solute concentration, and the dashed line is the assumed linear concentration [32]. Fick's first law expresses mass transfer from the solution phase to the solid surface:

$$J = -D\frac{\partial C}{\partial x}$$

where J is the mass flux to the surface (mol cm^{-2} s^{-1}), D is the coefficient of diffusion (cm^2/s), C is concentration (mol/cm^3), and x is the position coordinate perpendicular to the reference plane (cm). Thus,

$$J = \frac{1}{A}\frac{dn}{dt}$$

where *n* is the amount of material diffusing (mol), *t* is time (s), and *A* is the area of the reference plane (cm^2). Under steady-state conditions (*J* = constant), the integrated form of Fick's first law yields

$$\frac{dn}{dt} = -DA\frac{\Delta C}{\Delta x}$$

The term $D/\Delta x$ is often used as a mass-transfer coefficient. The thickness of the diffusion boundary layer (Δx) depends on the degree of agitation (i.e., flow velocity) and the viscosity. Vigorous agitation reduces the diffusion boundary-layer thickness and results in higher mass-transfer coefficients. The minimum value of Δx (i.e., the limiting boundary-layer thickness) has been calculated to be ca. 1×10^{-3} cm for violent agitation [33]. The value of the diffusion coefficient for aqueous solutions is ca. 1×10^{-5} cm^2/s for all species (simple cations, simple anions, neutral molecules, gases, etc.). Therefore, the mass-transfer coefficient should be in the range of 1×10^{-2} cm/s for diffusion through a limiting boundary layer. Besides minimizing Δx, the rate of leaching (dn/dt) can be increased by increasing the interfacial area or the concentration of the reacting species.

Figure 19. Concentration profile of the diffusion boundary layer for inward flux

C_b= concentration in bulk phase; C_s= concentration in solid phase.

Temperature. The temperature dependence of the reactions involved in liquid – solid extraction is best analyzed in terms of the Arrhenius law [34]:

$$k = ve^{-E_a/RT}$$

where *k* is the specific rate constant, *v* is the frequency factor, and E_a is the activation energy. The diffusion coefficient is also temperature-dependent and obeys an Arrhenius-type equation. However, the activation energy for diffusional processes is usually low: 8 – 13 kJ/mol for aqueous diffusion and 16 – 21 kJ/mol for viscous boundary-layer diffusion. In contrast, a process controlled by a surface chemical reaction exhibits a much higher activation energy (42 kJ/mol). Near ambient temperature, the reaction rate approximately doubles for a 10 °C increase in temperature when E_a= 50 kJ/mol.

Particle geometry is another important factor in liquid – solid processes because the reaction rate depends on the total surface area available:

$$\frac{dn}{dt} = Ak'C$$

where *A* is the surface area, *k´*is the rate constant, and *C* is the concentration. Sample geometry influences the way in which the surface area varies as the reaction proceeds. Shapes such as flat plates and disks exhibit a minimum variation in area, whereas samples with a cubic, spherical, or cylindrical wire-type geometry exhibit the greatest variations in area. The effect of sample geometry and the “shrinking core model” are treated in detail in [35-37].

Electrochemical Processes. In liquid – solid extraction (leaching reactions), electrochemical dissolution occurs at the surface of a conducting solid (i.e., metal M):

$$\text{Solid}(M) \rightleftharpoons \text{Ions in solution}(M^{n+}) + \text{Electrons in solid}(ne^-)$$

Figure 20 depicts the flow of electrons in the solid and the transfer of ions into solution. The electron acceptor is the oxidant used to dissolve the materials. Most metal sulfides and certain oxides (UO_2, MnO_2, SnO_2) are semiconductors and, therefore, their electronic properties favor electrochemical dissolution [38]. This involves the establishment of an internally short-circuited system, in which the solid assumes a mixed potential determined by the spatially separated anodic and cathodic processes.

Figure 20. Electrochemical dissolution at a solid surface

When conducting or semiconducting minerals in local electrical contact are subjected to leaching, a galvanic interaction may occur which causes enhanced corrosion of one or more members of the electrochemically coupled mineral regime and cathodic protection of other mineral constituents. Cathodic protection occurs because one material dissolves “sacrificially” and protects the other against dissolution by making it negative with respect to its equilibrium potential. The mineral with a lower “rest” potential will react anodically (dissolution), whereas cathodic behavior (passivation) may be imposed on the

mineral possessing the higher “rest” potential.

The cyanidation of gold and silver involves an electrochemical mechanism [39]. The dissolution of uranium dioxide in both acidic and alkaline carbonate solution is also electrochemically controlled [40-42]. Chalcopyrite [1308-56-1] ($CuFeS_2$) leaching in oxygenated ammoniacal solution has been explained in terms of an electrochemical model [43]. Galvanic coupling between pyrite (FeS_2) and chalcopyrite in a leaching environment results in enhanced dissolution of $CuFeS_2$ and passivation of the FeS_2 phase [44].

Biological Processes. The role of bacteria in leaching sulfidic deposits has long been recognized and is well documented, particularly in the leaching of copper (western United States and the former Soviet Union) and of uranium (Canada) [45].

The autotrophic aerobe Thiobacillus ferrooxidans has been associated with the leaching of base-metal sulfide minerals [46], [47]. It can utilize energy obtained by the metabolic oxidation of reduced inorganic sulfur and iron(II) and, simultaneously, catalyze the leaching of metal sulfides.

The oxidative leaching of metal sulfides (MS) with iron(III) ions is represented by

$$MS + 2\,Fe^{3+} \rightarrow M^{2+} + S + 2\,Fe^{2+}$$

The elemental sulfur produced forms a dense, tenacious coating on the partially reacted metal sulfide. This product layer is nonporous and makes the leaching rate extremely slow because it hinders diffusion. Oxidation of elemental sulfur is catalyzed by the bacteria present:

$$S + 3/2\,O_2 + H_2O \rightarrow H_2SO_4$$

The iron(II) ions produced during the oxidation of metal sulfides are also reoxidized with the acid of the bacteria:

$$2\,Fe^{2+} + 1/2\,O_2 + 2\,H^+ \rightarrow 2\,Fe^{3+} + H_2O$$

The mechanisms involved in bacterial leaching are still a matter of dispute; they may catalyze the reaction passively or may actively promote dissolution [48]. Extremely complex interactions occur among microorganisms, mineral substrates, and nutrients. *Thiobacillus ferooxidans* and *T. thiooxidans* show an amazing ability to adapt to the leaching environment. They can function over a wide range of pH and solution composition; some strains have adapted to tolerate high concentrations of metal ions under very acidic conditions. For example, *T. ferrooxidans* has been able to adapt to iron and arsenic concentrations of 50 and 20 g/L, respectively, at a pH of 0.5 [49]. The temperature range for optimum *T. ferrooxidans* and *T. thiooxidans* activity is limited and lies between 25 and 45 °C [50]. A chemoautotrophic, thermophilic microorganism (*Sulfolobus*) has been isolated and is effective above 60 °C [51].

Bioleaching is attracting attention for the treatment of refractory precious-metal ores and concentrates [52-54]. Some gold ores and concentrates containing sulfide minerals (i.e., pyrite and arsenopyrite) are refractory to (i.e., withstand) conventional cyanidation. Biooxidation of the sulfide prior to cyanidation has proved to be effective for gold and silver recovery from refractory materials. Bioleaching techniques have been developed for the heap leaching of ores and the leaching of concentrates in stirred tanks [49].

3.3. Typical Processes and Equipment

Typical examples illustrating the use of liquid – solid extraction (leaching) are (1) agitation leaching of an oxidized gold ore with alkaline cyanide solutions, (2) pressure leaching of a zinc sulfide concentrate and (3) biological leaching of a refractory gold ore.

3.3.1. *Agitation Leaching of an Oxidized Gold Ore*

Selection of the processing methods for gold ores depends on economic, metallurgical, and engineering considerations. For a detailed description of gold production, see ⟶ Gold, Gold Alloys, and Gold Compounds. Conventional milling (agitation leaching) is generally preferred to heap leaching for higher grade deposits that justify the added costs of crushing and grinding [55]. Agitation leaching also maximizes gold recovery by increasing the exposure of metal surfaces to the leaching solution. The size of the agitation reactor depends on the feed rate and the time necessary to achieve the desired degree of extraction. Usually, a stagewise (semibatch) operation is used to balance fluctuations in the feed composition and to control the continuity of output.

Figure 21 shows a simplified flow sheet for a leaching circuit consisting of six agitation vessels. The ore is ground to give a particle size that yields acceptable extraction levels (>90 %). A ball mill is linked in closed circuit with a hydrocyclone classifier. The ground and sized product is thickened to between 45 and 50 % solids prior to leaching. The overall gold-leaching reaction is

Figure 21. Flow sheet of an agitation leaching circuit for precious-metal ores

a) Ball mill; b) Cyclone; c) Thickener; d) Agitated leaching vessel

$$4\,Au + 8\,CN^- + O_2 + 2\,H_2O \rightleftharpoons 4\,Au(CN)_2^- + 4\,OH^-$$

Lime (or caustic), sodium cyanide, and air are introduced in the pulp to achieve the desired dissolution. In each leaching stage, air is mixed vigorously into the pulp by air agitation or mechanical impellers.

The draft-tube circulator – aerator shown in Figure 22 combines efficient oxygen transfer and effective mixing [56]. The agitator shaft and impeller are located inside a hollow tube, and compressed air is introduced immediately below the impeller. These systems are used in deep tank mixing.

Figure 22. Schematic of a draft-tube submerged turbine aerator

a) Agitator shaft; b) Impeller; c) Draft tube

The pulp leaving the last leaching vessel proceeds to a liquid – solid separation step to prepare the leach solution for metal recovery and to wash the solids free of dissolved gold. This can be accomplished, for example, by countercurrent decantation (CCD) washing or filtration which, however, require a high capital investment. Certain pulps do not respond readily to liquid – solid separation. New carbon-in-pulp (CIP) technology overcomes these limitations and has gained widespread acceptance in the processing of gold ores [57], [58]. It is effective for low- and variable-grade solutions.

A typical CIP extraction circuit is shown in Figure 23. Ore leached as shown in Figure 21 is fed into the CIP circuit. The objective is to adsorb the dissolved aurocyanide complex onto activated carbon in a countercurrent fashion; the process consists of the following steps:

1. Prescreening
2. Multistage, countercurrent carbon adsorption
3. Carbon elution and reactivation
4. Gold reduction (electrowinning)

Figure 23. Flow sheet for a carbon-in-pulp (CIP) gold—recovery circuit

a) Screen; b) Interstage screen (20 mesh); c) Carbon transfer vessel; d) Carbon stripping column; e) Carbon reactivation kiln; f) Gas-fired exchanger; g) Heat exchanger; h) Fresh stripping solution; i) Pregnant stripping solution; j) Electrowinning

Before the pulp enters the adsorption circuit, it is prescreened to remove coarse material that might otherwise contaminate the loaded carbon and to eliminate waste that might block the interstage screens (b). During subsequent adsorption, carbon moves stepwise in the opposite direction to the pulp. The grains of carbon are coarser than the ore particles and can, therefore, be separated from the pulp by simple screening on interstage screens. Fresh carbon is added to the last adsorption vessel; when sufficiently loaded with gold, this is conveyed batchwise from tank to tank by airlifts or recessed impeller pumps. The carbon in the first adsorption vessel is highly loaded with gold and is transferred to a stripping column (d) where gold is eluted from the carbon by using high-pressure, high-temperature NaOH/NaCN solutions, or by alcohol stripping. The carbon is reactivated in a kiln (e) and returned to the last adsorption vessel. Gold is obtained from the pregnant stripping solution by electrowinning (j). Carbon is separated from the pulp by screening.

3.3.2. *Pressure Leaching of Zinc Sulfide Concentrates*

The world's first commercial zinc sulfide pressure leaching plant was built by Cominco in Canada [59]. Zinc sulfide [1314-98-3] concentrates are leached oxidatively in an autoclave reactor to produce a zinc sulfate solution and elemental sulfur, according to the following reaction:

$$ZnS + H_2SO_4 + 1/2\,O_2 \rightarrow ZnSO_4 + S + H_2O$$

Figure 24 shows a flow sheet of the zinc pressure leaching process. Reground zinc concentrates, typically containing 49 % Zn, 11 % Fe, 4 % Pb, and 33 % S, are fed continuously to the autoclaves with preheated spent electrolyte containing 150 g/L of sulfuric acid. The autoclave reactor contains four compartments and measures 3.7 m in diameter and 15.2 m in length. It consists of a mild-steel outer shell lined with lead, a refractory cloth, and acid-resistant brick (Figure 25). Pulp enters at one end and is discharged at the other after passing through the four compartments, each of which is equipped with a mechanically driven impeller to provide agitation.

Figure 24. Flow sheet for the zinc pressure leaching process

a) Service cluster; b) Service nozzles; c) Motor drive assembly; d) Agitator nozzle, e) Agitator; f) Compartment divider; g) Dip pipe; h) Support saddle

Courtesy of Sherritt Gordon Mines Ltd.

The slurry is pumped to the first compartment of the autoclave at the delivery pressure up to 1.85 MPa. Preheated spent electrolyte from the tank house is introduced at ca. 1.5 MPa and 70 °C. Heat of reaction elevates the temperature to 145 – 155 °C. The oxygen partial pressure is maintained at ca. 0.75 MPa with a total overpressure of 1.3 MPa. The system is designed for a leach retention time of about 100 min and for 98 % zinc extraction. The zinc is extracted into solution as zinc sulfate; sulfide is oxidized to elemental sulfur in the molten state, and iron and lead are rejected into the residue as insoluble plumbojarosite [$PbFe_6(SO_4)_4(OH)_{12}$]. The complete process chemistry is described in [60].

Oxidative pressure leaching has been applied to the treatment of sulfidic precious-metal oresand concentrates which are refractory to conventional cyanidation [24], [25]. Pressure oxidation is an effective way of “chemically” liberating precious metals and offers an attractive alternative to roasting.

A pressure oxidation process for pretreatment of a refractory gold ore has been developed by the Homestake Mining Company. The commercial plant can treat 3000 t/d of ore by pressure oxidation and carbon-in-leach cyanidation [61].

3.3.3. *Bioleaching of Refractory Precious-Metal Concentrates*

One of the most promising applications of bioleaching technology is the pretreatment of refractory precious-metal ores and concentrates. Continuous biological preoxidation of sulfidic ores and concentrates is being developed to compete with pressure oxidation and roasting. Bioextractive processes have been proposed for leaching concentrates of lead sulfide [62], copper – nickel complex sulfides [63], and chalcopyrite [64].

Many gold ores and concentrates that contain sulfidic minerals such as pyrite (FeS_2) and arsenopyrite [1303-18-0] (FeAsS) are refractory to conventional cyanidation, partially because the gold is finely disseminated within the sulfide matrix in a submicroscopic form or in solid solution, and as such may not be liberated even with fine grinding. Chemical dissolution of the sulfide matrix exposes the gold for subsequent extraction by cyanidation. Certain bacteria can metabolize and dissolve pyrite and arsenopyrite under acidic conditions according to the following exothermic reactions:

$$2\,FeS_2 + 15/2\,O_2 + H_2O \rightarrow 2\,Fe_3^{+} + 2\,H^{+} + 4\,SO_4^{2-}$$

$$FeAsS + 7/2\,O_2 + H^{+} + H_2O \rightarrow Fe^{3+} + SO_4^{2-} + H_3AsO_4$$

Bacterial strains (e.g., *Thiobacillus ferrooxidans*) have been adapted which can tolerate high concentrations of iron and arsenic at low pH [49]. However, temperature continues to have a regulating role in determining the activity of *T. ferrooxidans.* The heat generated by the exothermic bacterial oxidation of sulfides is normally removed via cooling coils placed in the bioleaching reactor.

Figure 26 is a flow sheet of a biological preoxidation circuit for processing sulfidic material to improve gold and silver recovery by cyanidation.

Figure 26. Flow sheet of a bioleaching process for treating refractory precious-metal concentrates

a) Conditioning tank; b) Thickener; c) Filter; d) Repulp tank; e) Sump; f) Ball mill; g) Cyclone

Courtesy of Albert Bruynestyne.

The bioleaching section consists of two parallel streams, each with four reactors divided into three stages; total retention time is 96 h in each line. The first stage employs two reactors in parallel (retention time 48 h). The second and third stages use a single reactor each (retention time, 24 h per reactor).

Leaching efficiency is improved by feeding reground concentrate into the bioleaching circuit. The feed will run 90 % <37 μ (400 mesh) and will be adjusted to 20 % solids. Because the oxygen required for leaching pyrite and arsenopyrite is fairly high, the reactors must be designed for efficient mass transfer of oxygen. Air is sparged into the reactors, and mechanical agitation ensures adequate oxygen uptake.

The leached slurry leaving the last reactor is concentrated to provide a thickened solid which is neutralized prior to cyanidation. A series of limestone – lime neutralization steps delivers a product slurry at about pH 10 for feed to cyanidation. A portion of the bioleach residue thickener overflow is returned to the bioleaching circuit. Another portion is bled to the solution treatment section to eliminate iron, arsenic, and sulfate, from the system. Another series of limestone – lime neutralization steps is employed to treat the bleedstream. A tailing containing primarily gypsum, jarosite, and ferric arsenite is thickened for disposal. The resulting neutral solution is added to the ground feed.

[Top of Page]

4. Extraction with Supercritical Fluids

Gerd Brunner

Gaseous material of high density can be used industrially in the same way as liquid solvents [65]. At moderate pressure (30 – 50 MPa) and close to the critical temperature T_{cr}, the densities of gases are comparable to those of liquids. These dense gases ($T > T_{cr}$) or compressible fluids ($T < T_{cr}$) display a high solvent capacity. Their mean intermolecular distance is so small that molecular interactions are of importance. The properties of a compressed substance in the region of the critical temperature can be modified by changes in pressure and/or temperature in such a way that the substance behaves either as a normal low-density gas or as a liquid.

A large difference in volatility exists between the compressed gas solvent and the substances dissolved in it. After expansion, almost all of the solvent can be separated. Thus, the properties of gases in the supercritical state (i.e., $T > T_{cr}$; $p > p_{cr}$) and liquids in the subcritical state close to the critical temperature (i.e., $0.95 \cdot T_{cr} < T < 1 \cdot T_{cr}$; $p < p_{cr}$), largely correspond to those of a solvent. These substances are of potential use in (extraction) processes employing solvents. The operating temperature of such a process is largely determined by the critical temperature. Carbon dioxide (T_{cr} = 31 °C, p_{cr}= 7.3 MPa) is a readily available gas with favorable properties. The process is known as *gas extraction* or *supercritical-fluid extraction* and is mainly of interest for the separation of temperature-sensitive mixtures of low volatility or mixtures in which liquid solvent residues must be avoided.

4.1. Principles

Compressed gases can be used as solvents in many different industrial processes. The most common application of high-density compressible fluids is as physical solvents in one-stage processes. However, multistage processes and countercurrent operations are also possible, and compressed gases can be used as solvents for chemical reactions.

Types of Processes. In single-stage processes (Fig. 27 A), one or more components are extracted from the feed mixture in an extraction vessel (a) with the aid of the compressed gas. The separation factor α for the components and the residue approaches infinity. The separation factor for components A and B of a mixture (e.g., the extract and the residue) is given by

$$\alpha_{AB} = \frac{x_A^{I}}{x_A^{II}} \cdot \frac{x_B^{II}}{x_B}$$

where x denotes the mole fraction of the substance and the indices I and II indicate different phases or product streams. The extract product is obtained from the compressed gas by means of a change of state or by absorption/adsorption in a separator (b). The gas is then readjusted to the extraction conditions in the compressor (c) and recycled. Examples of such processes are the extraction of alkaloids [66], hops [67], and edible oils [68]; the deoiling of lecithin; and the extraction of flavors [69] from solids that are insoluble in the compressed gas. The extraction of lignin also takes place in a single step but involves a chemical reaction.

Figure 27. Schematic diagrams of gas extraction

A) Single-stage extraction; B) Multistage extraction; C) Continuous multistage contercurrent extraction

a) Extraction vessel; b) Separator, c) Compressor

If the separation factor is too small to permit single-stage extraction, *multistage extraction* can be used (Fig. 27 B). Either the extraction or separation conditions can be modified in several steps so that different components or mixtures can be consecutively extracted or separated. Examples are the refining of used oil [70], the fractionation of edible oils [71], and the deasphalting of oil [72]. In the refining of used oil, the fluid fraction of the oil is first separated from the solid contaminants with ethane. The pressure is then reduced and the temperature increased in several successive stages to separate fractions, according to either their pressure-dependent solubility in ethane or their volatility.

Supercritical gaseous solvents have also been studied for the production of synthetic fuels from coal, oil shale, and heavy oil [73]. Solvents such as supercritical toluene, tetralin, water vapor, and hydrogen can dissolve soluble components and pyrolysis products. The extract can then be fractionated by means of changes of state.

In the case of low separation factors, extraction may be performed as a *continuous multistage countercurrent process* (Fig. 28 C). This type of gas extraction is comparable to liquid – liquid extraction in countercurrent columns and can be treated analogously (⟶ Liquid–Liquid Extraction – Apparatus).

Figure 28. Phase diagrams of binary systems with a continuous critical curve (A – C) or an interrupted critical curve (D – F)

A_1= gaseous phase; A_2= liquid phase (rich in component 1); A_3= liquid phase (rich in component 2); B_1= triple point of component 1; B_2= triple point of component 2; C_1= critical point of component 1; C_2= critical point of component 2; K = critical end point of three-phase line (liquid – liquid – gas); x_2= mole fraction of component 2; ⇒vapor-pressure curve of pure component; – – – critical curve; hatching indicates two-phase areas

Examples of such separations are the laboratory-scale concentration of ethanol from dilute aqueous solutions [74] and the separation of monoglycerides from diglycerides [75].

Solvent Properties. The solvent capacity of compressed gases is primarily determined by their density. In the region of the critical temperature, small changes of temperature or pressure can be used to vary the density within wide limits. Close to the critical point, the latent heat of vaporization is very low; this means that separation of the extract from the solvent is simple and consumes very little energy. Furthermore, the properties of the compressed gas are favorable for transport, i.e., low viscosity, high diffusion coefficient, and high thermal conductivity (Table 4).

Table 4. Properties of solvents used for gas extraction

State of solvent	Density ϱ, g/cm^3	Viscosity η, g cm^{-1} s^{-1}	Diffusion coefficient D, cm^2/s
Gas (0.1 MPa, 25 °C)	$(0.6 – 2)\times10^{-3}$	$(1 – 3)\times10^{-4}$	0.1 – 0.4
Compressed gas			
p_{cr}, T_{cr}	0.2 – 0.5	$(1 – 3)\times10^{-4}$	0.7×10^{-3}
4 p_{cr}, ≈ T_{cr}	0.4 – 0.9	$(3 – 9)\times10^{-4}$	0.2×10^{-3}
Liquid (organic solvent, water at 0.1 MPa, 25 °C)	0.6 – 1.6	0.002 – 0.003	$(0.2 – 2)\times10^{-5}$

In general, the solvents used for gas extraction are either supercritical or contain a supercritical substance as their major component. A number of gases are available with critical temperatures below 100 °C:

ethylene	9.5 °C
carbon dioxide	31 °C
ethane	35 °C
nitrous oxide	36.5 °C
propane	96.8 °C

Mixtures of these gases yield solvents with intermediate critical temperatures. Relatively low concentrations (1 – 15 wt %) of polar substances, such as ethanol, can be used as entrainers. They cause specific interactions which improve the solvent capacity for polar substances considerably [76].

A compressed gas separates a mixture of substances primarily according to their molecular mass or volatility. Molecular interactions between the gas and the dissolved substances are of secondary importance. The gas solvents are generally only slightly polar; highly polar substances such as water are much less soluble in them than nonpolar substances. For a given solvent, the solubility decreases with increasing polarity of the solute. Another important factor affecting separation is the solubility of the gas solvent in the liquid phase formed. Incorporation of solvent molecules into the liquid phase causes considerable structural changes. These changes include a decrease in the attractive interactions between the molecules that are to be dissolved because of an increase in their mean separation.

4.2. Process Design

The most important data required for the design of a gas extraction (pressure, temperature, type and quantity of solvent, energy requirements) can be obtained from phase equilibria, mass transfer data, and a thermodynamic analysis of solvent circulation.

Phase Equilibria. The binary phase equilibria between a supercritical component (solvent) and the dissolved substances are the most important factors in gas extraction. The equilibria can usually be divided into two types, according to whether the critical curve is continuous (Fig. 28 A – C) or interrupted (Fig. 28 D – F). The equilibrium concentrations can be determined directly from the *p, x* curves at constant temperature. The solvent capacity of the gaseous solvent increases exponentially with pressure over a relatively wide range (Fig. 29). The solvent capacity of a gas generally increases with its density. Thus, at constant pressure, the solubility of a substance in a compressed gas can increase or decrease with increasing pressure, depending on whether the influence of the decrease in density or the increase in vapor pressure dominates.

Figure 29. Solubility of oleic acid in ethylene (v_i = molar volume of ethylene) as a function of temperature (⇒) or pressure (— — —)

a) 20 °C; b) 54.8 °C; c) 102.2 °C; d) 126.7 °C; e) 10 MPa; f) 15 MPa; g) 20 MPa; h) 25 MPa; i) 30 MPa

Although substances of low volatility are more soluble in compressed gases than is to be expected on the basis of their vapor pressure, their absolute concentrations are relatively low. For example, at 70 °C and 30 MPa the concentration of dissolved triglycerides (the main constituent of edible oils) in carbon dioxide only reaches 1 wt %. Solubility can be effectively increased to achieve complete miscibility by choosing an appropriate solvent (Fig. 30 A) or by adding an entrainer to the compressed gas (Fig. 30 B).

Figure 30. Solubility increase in solvent mixtures

A) Miscibility of extract and gas (solvent) mixtures as a function of pressure

Curves indicate phase boundaries for an extract which is (a) only slightly soluble, (b) moderately soluble, or (c) very soluble in the gas

B) Ternary phase diagram showing the increase in solubility produced by an entrainer at pressure p_1

Binary solubility of extract in gas according to case a, b, and c

The equilibrium solubility in fluid phases can be correlated over a wide range of conditions of state by using three-parameter equations of state of the Van der Waals type. Modified forms of the Redlich – Kwong equation and the equation of state according to Peng – Robinson are most commonly used. A general view of the phase behavior of a one-component system can be obtained from a small number of measurements by using these equations. To describe mixtures, mixing rules for binary mixtures are introduced which take into consideration the interactions between the two different types of molecules. These interaction parameters are determined by fitting with experimental equilibrium values. This method is inadequate for describing the critical curves or phase equilibria of associating molecules.

Mass Transfer. Mass transfer under the conditions used for gas extraction has not been as intensively investigated as phase equilibria. However, to a first approximation, it can be assumed that if the physical characteristics of the appropriate mixtures are used, the dimensionless correlations for liquid solvents are applicable. The flow rates of the compressed gas in the extraction vessel are ca. 10^{-2} m/s, whereas flow rates of 10 – 15 m/s are found in pipes because the viscosity is low. Extraction of solids is usually governed by the diffusion of solvent and solute within the solid. Accordingly, the extraction rate decreases exponentially with time (Fig. 31). If the material is comminuted (e.g., by grinding) and a high concentration of the substance to be extracted is present, this extraction phase may be preceded by a phase with a constant extraction rate. The resistance to transport in the solvent phase and the stationary mass transfer in a bulk solid can be calculated for a constant extraction rate with the following mass-transfer equation:

$$Sh = 2 + 1.1 Sc^{1/3} \cdot \mathrm{Re}^{0.6}\,;\; Sh = \left(\beta_a \cdot d\right) / D_G$$

where *Sh* is the Sherwood number, *Sc* the Schmidt number, *Re* the Reynolds number, β_a the outside mass-transfer coefficient, *d* the particle diameter, and D_G the diffusion coefficient of the gas.

Figure 31. Time course of the extraction of rapeseed oil from prepressed rapeseed using supercritical carbon dioxide

Quasistationary and nonstationary approximations can be calculated for the nonstationary fraction (decreasing extraction rate) [77]. The quasistationary approximation is

$$\frac{c_m - c_\infty}{c_A - c_\infty} \approx \exp\left(\frac{-kA}{M_s c_A} \cdot t\right)$$

where

A = surface area for mass transfer

c_A = initial concentration of extract (solute) in solid

c_m = concentration of extract in the solid at time t

c_∞ = concentration of extract in the bulk solvent

k = mass-transfer coefficient
M_s = relative molecular mass of extract (solute)
t = time

The nonstationary approximation is

$$\frac{m}{m_c} = c_q[1 - \exp(-EFo)]$$

where

c_q = tabulated values of the approximation [78]
E = tabulated values of the approximation [78]
Fo = Fourier number
m = extract content of solid
m_c = initial extract content of solid

The entire process can be represented by a model analogous to that used for drying [79]. Measurements of mass transfer have been made on glycerides in continuous countercurrent extraction with fluid phases [80]. At a flow rate of 10 mm/s in an empty tube, two or three separation stages per meter are required for bubble-cap plates or a Sulzer packing, respectively.

The circulation of gaseous solvent depends primarily on whether separation of the extract is achieved by expansion or by absorption/adsorption. In absorption/adsorption the energy consumption for gas circulation can be calculated from the pressure loss of ca. 1 – 2 MPa at an extraction pressure of 30 MPa. The energy requirement for obtaining the product corresponds essentially to that needed to separate the adsorbent or absorbent from the extract.

The use of expansion for product separation can extend into the two-phase region. The subsequent pressure increase then occurs when the solvent is in the liquid state. However, expansion may also remain within the supercritical region, the subsequent pressure increase then results in gas compression (gas state) [81]. Both types of circulation are shown in Figure 32 in the form of temperature – entropy diagrams.

Figure 32. Solvent circulation in gas extraction (temperature – entropy) diagrams

B) Pump process

A ⟶ B = compression with pump; B = extraction; B ⟶ C = expansion; C ⟶ D = evaporation; D = separation of extract/solvent; D ⟶ A = condensation

4.3. Equipment

The temperatures and pressures used in gas extraction plants lie within the ranges commonly used in industry. Special features are the large amounts of circulating gas, the increasing strain imposed on the pressurized containers used in batch processes, and the feed devices. Various quick-sealing systems are used in solid extraction for the rapid and complete filling and emptying of the extraction vessel. Examples are shown in Figure 33. Devices such as screw presses and lock – hopper systems have been proposed for continuous feeding and product removal. Lock – hopper systems have been used successfully in industrial plants. However, screw presses still have to be implemented on an industrial scale as feeding devices because leakage of gas is difficult to avoid.

Courtesy of R. Eggers.

Commercial plants for solid extraction have so far only been used in the food industry and employ solely carbon dioxide as a solvent. The first plant was opened in 1981 by HAG (General Foods) in Bremen (Federal Republic of Germany) for the decaffeination of coffee (see also ⟶ Coffee – Decaffeination); a second plant followed in 1988 in Houston (United States). Plants for the production of hop extract are operated by Barth, Wolnzach, and SKW in Münchsmünster (Federal Republic of Germany). A plant for the decaffeination of black tea was installed in 1988 by SKW.

Hop extract is also produced with liquid carbon dioxide in a virtually critical state (⟶ Beer – Processing of Hops and Hop Products); such plants can be found, for example, in England and Australia. Critical liquefied gases have also been used as solvents to separate liquid mixtures. Examples include deasphalting with propane, removal of triglycerides from fish oils with propane in the Solexol process, and more recently, the residuum oil supercritical extraction (ROSE) process for extracting residual oil with butane and/or pentane (⟶ Asphalt and Bitumen – Solvent Separation Methods). In a process for methyl ethyl ketone used by Idemitsu (Japan), the intermediate product 2-butanol is extracted from an aqueous solution with 1-butene under supercritical conditions.

1. Equilibrium of Gas Solubility

1.1. Introduction

Absorption is the uptake of gases by a solvent. Adsorption means accumulation on the surface of a solid (→ Adsorption). The equilibrium of solubility describes the distribution of absorbed materials between the vapor and liquid phases (VLE i.e., vapor – liquid equilibrium). Depending on its volatility, the solvent may appear in the vapor phase; this phenomenon will only be mentioned tangentially (see Section 5.3 and 5.4).

The interaction of absorbed materials with the solvent can be physical or chemical in nature (van der Waals forces, dissociation, neutralization, oxidation). In *physical absorption*, the gas molecules are polarized but remain otherwise unchanged. In *chemical absorption*, they are also chemically converted. The type of interaction critically affects the solubility equilibria and the shape of the absorption isotherms.

Chemical absorption entails greater changes in enthalpy than physical absorption, in which the enthalpy change is about equivalent to the enthalpy of condensation. Depending on which interaction predominates, the terms physical or chemical solubility, and even physical or chemical solvent, are used. The latter designation can be misleading because one and the same solvent exhibits chemical solubility for some gases (e.g., carbon dioxide or hydrogen sulfide) and physical solubility for others (e.g., hydrogen or methane).

Solubility equilibria are governed by the general thermodynamic condition that the entropy is at its maximum in a closed system. Thus, at equilibrium the molar Gibbs energy G is

$$\delta\left(\sum_i n_i G\right)/\delta n_i = 0 \quad [T,p = \text{const.}] \tag{1}$$

in all phases, and the fugacity is

$$f^{G} = f^{L} \text{ and } f_i^{G} = f_i^{L} \tag{2}$$

in the gas and liquid phase. This chapter deals first with the fugacity of the gas in the gas and

liquid phase, as well as with the activity of the liquid phase. The laws governing physical and chemical solubility equilibria are then discussed.

1.2. Gas-Phase Fugacity

The fugacity f_i of component i in the gas phase is defined by

$$dG_i = RT\,\mathrm{d}\ln f_i = v_i^{\mathrm{G}}\,\mathrm{d}p \tag{3}$$

and a boundary condition

$$f_i = y_i p, \text{ at } p \to 0 \tag{4}$$

Fugacity cannot be measured directly but is determined from an equation of state that describes the gas mixture in question.

$$\ln\frac{f}{p} = \int_0^p \left(\frac{V^{\mathrm{G}}}{RT} - \frac{1}{p}\right)\mathrm{d}p = \int_0^p \frac{z-1}{p}\,\mathrm{d}p \tag{5}$$

To solve this, either the molar volume v^{G} of the gas mixture from the equation of state or the compressibility factor z is substituted. The fugacity of component i is calculated from

$$\ln f_i/y_i = \ln f - \sum_{k\neq i} y_k\,(\delta \ln f/\delta y_k) \tag{6}$$

In the partial derivation, all components except the kth and ith are kept constant. Equations (5) and (6) have been solved and published for many equations of state. Solutions for the van der Waals equation, the virial equation with one or two constants, the cubic (Redlich – Kwong, Soave and Peng – Robinson), and the complex [Benedict – Webb – Rubin (BWR) and BWR – Starling] equations of state will be found in [1].

The generalized method of calculation according to Hayden and O'Connell, based on the virial equation, appears in [2]. All thermodynamic data and many binary interaction parameters required for the calculation are listed there for many gases. While the applicability of this method is limited, the calculations are not too time-consuming. The method is not suitable for the critical region, and its application is confined to the following pressures:

$$p/p_{\mathrm{c}} \leq 0.5T/T_{\mathrm{c}} \tag{7}$$

For gas mixtures, a weighted average is used for the critical pressure p_{c} and the critical temperature T_{c}

$$p_{\mathrm{c}} = \sum_i y_i p_{c,i} \text{ and } T_{\mathrm{c}} = \sum_i y_i T_{c,i} \tag{8}$$

In the model considered most efficient at the moment, the fugacity is calculated from two terms [3]:

$$\log(f/p) = [\log(f/p)]^{(0)} + \omega\,[\log(f/p)]^{(1)} \tag{9}$$

where ω is the component-specific acentric factor. The logarithmic terms in square brackets have been published as a function of the reduced temperature and the reduced pressure [1], [4]. Unfortunately, this method can be used only for single-component gases; computer programs are required to calculate the fugacity in gas mixtures. A modification of the method has been published along with the corresponding rules of mixing [5]. For polar components, an additional polar factor is introduced.

Simulation programs calculate the fugacity by several methods. The user can select a suitable method but must be mindful of the areas of application to avoid gross errors.

The *virial equation* offers a simple method of calculation and is very popular. However, it is not suitable in the critical region or for liquids. Outside the critical region, predicted compressibility factors are reproduced with deviation <2 % for pure components <3 % for weakly polar mixtures, and <5 % for highly polar mixtures. This accuracy can be achieved in the following region of application:

$$p_{\mathrm{r}} < T_{\mathrm{r}} - 0.65 \text{ for } T_{\mathrm{r}} < 1 \tag{10}$$

$$p_{\mathrm{r}} < 1.05T_{\mathrm{r}} - 0.35 \text{ for } T_{\mathrm{r}} > 1 \tag{11}$$

For the critical data of gas mixtures weighted averages according to Equation (8) are used for the reduced pressure ($p_{\mathrm{r}} = p/p_{\mathrm{c}}$) and for the reduced temperature ($T_{\mathrm{r}} = T/T_{\mathrm{c}}$). Among the *cubic equations* of state, Soave and Peng – Robinson are widely employed. They can also be used sucessfully in the critical region, but binary interaction parameters are required for gas mixtures. Benedict – Webb – Rubin is suitable for hydrocarbons, and Lee – Kesler – Plöcker is recommended for broad ranges of pressure and temperature ($0 < p_{\mathrm{r}} < 10$ and $0.3 < T_{\mathrm{r}} < 4$) [4].

In the commercial programs Process, Pro II, and Aspen, one method is offered as default for the fugacity calculation, and the user can select another. If the correct method is in doubt, the selected method must be checked against experimental data in the area of interest.

1.3. Liquid-Phase Fugacity and Activity

The *fugacity of dissolved component i* in the liquid phase is given by

$$f_i^{\mathrm{L}} = \gamma_i x_{\mathrm{i}} f_i^0 \exp \int_{p^{\mathrm{r}}}^{p} \left(v_i^{\mathrm{L}} / RT \right) \mathrm{d}p \tag{12}$$

The exponential term represents the effect of gas-phase pressure and is called the *Poynting factor*. Here, v_i is the molar volume of component i in the liquid phase, and the integration is carried out from the reference pressure p^{r} to the pressure of the system p. The *activity coefficients* γ_i are needed to correct the real liquid phase; they are related to the molar excess Gibbs energy G^{E} as follows:

$$G^{\mathrm{E}} = RT \sum_i x_i \ln \gamma_i \tag{13}$$

There are many G^{E} models for calculating the activity coefficients γ_i in the liquid phase. A key advance was made by Wilson in 1964, who introduced the local concentration that led to the development of the powerful NRTL (nonrandom two liquid), ASOG (analytical solution of groups), UNIQUAC (universal quasi-chemical equation) and UNIFAC (UNIQUAC functional group activity coefficient) models [6–9].

The following two conventions are preferred for normalizing the activity coefficients γ_i and the standard fugacity f_i^0:

Pure Liquid Component *i*. The activity coefficients γ_i are

$$\gamma_i = 1 \text{ if } x_i \to 1 \tag{14}$$

and the standard fugacity is

$$f_i^0 = p_i^0 \varphi_i^0 \exp \left[\left(p^{\mathrm{r}} - p_i^0 \right) \bar{v}_i^{\mathrm{L}} / RT \right] \tag{15}$$

where $\bar{v}_i^{\mathrm{L}}$ is the average molar volume of the dissolved component i in the liquid phase, p_i^0 is the saturated vapor pressure of the pure component i at temperature T and the fugacity coefficient of this vapor $\varphi_i^0 = f/p$ is calculated according to Equation (5). This *symmetrical normalization* can be used as long as the pure component i forms a liquid, hence, in the temperature range of its triple point up to the critical temperature. At low to moderate pressure,

$$\varphi_i^0 = 1, \text{ so that } f_i^0 = p_i^0 \tag{16}$$

and the Poynting factor $\to 1$ so that Raoult's law follows from Equations (12) – (15):

$$p_i = x_i p_i^0 \ (\text{if } x_i \to 1) \tag{17}$$

The standard fugacities of many liquids have been determined for the reference pressure $p^{\mathrm{r}} = 0$ and generalized by using the theorem of corresponding states as a function of the reduced temperature T_{r} and the acentric factor ω.

$$f_i^0 / p_{c,i} = F\left(T_{\mathrm{r},i}, \omega_i\right) \tag{18}$$

By extrapolation of Equation (18), the utility of symmetric normalization has been expanded beyond the critical temperature [2].

Infinitely Dilute Solutions. The activity coefficients are chosen as

$$\gamma_i = 1 \text{ if } x_i \to 0 \tag{19}$$

and the standard fugacity as

$$f_i^0 = H_{i,\mathrm{L}} \tag{20}$$

$H_{i,\mathrm{L}}$ is Henry's law constant of component i in the solvent L because, at low pressure, Equation (12) becomes Henry's law

$$p_i = x_i H_{i,\mathrm{L}} \ \ (x_i \to 0) \tag{21}$$

For gaseous component i in solvent L, the Henry's law constant depends only on temperature and can be determined from the solubility equilibria (see Section 1.4). No temperature limit exists to this so-called unsymmetric normalization because for gases, Henry's law constant can also be measured in the supercritical region. Henry's law constant is determined from solubility data. To do so, the ratio f_i/x_i is plotted vs. x_i and extrapolated to $x \to 0$. Henry's law

constant holds exactly only if the total pressure $p = p_L^0$ = vapor pressure of the solvent.

At higher pressure of the dissolved component, Henry's law constant is corrected similar to the Poynting factor according to the Krichevsky – Kasarnovski equation.

$$\ln H_{i,\mathrm{L}}(p) = \ln H_{i,\mathrm{L}}\left(p_{\mathrm{L}}^0\right) + v_i^\infty\left(p - p_{\mathrm{L}}^0\right)/RT \quad (22)$$

At infinite dilution the molar volume v_i^∞, is assumed to be constant over the entire range of pressure. The Krichevski – Illinskaya equation applies to a larger range of concentration:

$$\ln H_{i,\mathrm{L}}(p) = \ln H_{i,\mathrm{L}}\left(p_{\mathrm{L}}^0\right) + v_i^\infty\left(p - p_{\mathrm{L}}^0\right)/RT + C\left(x_{\mathrm{L}}^2 - 1\right) \quad (23)$$

The constant C is fitted to the experimental data. Henry's law applies at low loading and is used frequently. Raoult's law is used only rarely, for example, in the region of condensation if loading becomes extremely high.

Both laws are obeyed over the entire range of concentration $0 < x_i < 1$ only by ideal solutions. The deviation from Henry's and Raoult's laws in real solutions between the boundary values is demonstrated in Figure 1 by the solubility of carbon dioxide in methanol and in Figure 2 by the solubility of hydrogen sulfide in N-methylpyrrolidone. The ratio p_i/x_i is shown in the figures as a function of the mole fraction x_i for several temperatures; in real solutions, considerable deviations from ideality occur.

Figure 1. Solubility of carbon dioxide in methanol
Data from [14]; lines calculated with UNIQUAC
a) $t = -60\,°C$; b) $t = -40\,°C$; c) $t = -20\,°C$; d) $t = 0\,°C$; e) $t = 25\,°C$; f) $t = 50\,°C$; g) $t = 75\,°C$

Figure 2. Solubility of hydrogen sulfide in N-methylpyrrolidone
Data from [10]; lines calculated with UNIQUAC
a) $t = 0\,°C$; b) $t = 10\,°C$; c) $t = 20\,°C$; d) $t = 30\,°C$; e) $t = 40\,°C$

The calculated lines show that measured values can be reproduced quite accurately once both phases have been corrected in the following manner.

The fugacity of the gas phase is determined from the virial equation, and the activity coefficients in the liquid phase are calculated with UNIQUAC; the temperature-dependent binary UNIQUAC parameters are then fitted to the measured data (for details, see [2]).

1.4. Physical Absorption

In physical absorption, the concentration of dissolved gases in the solvent increases in proportion to the partial pressure of these gases; i.e., it follows Henry's law (Eq. 21).

Henry's law constant $H_{i,\,\mathrm{L}}$ has the same dimensions as the vapor pressure p_i^0 and is numerically equal to it in ideal solutions. In real solutions, the numerical value of Henry's law constant depends on the solvent. While Henry's law constant has physical meaning even at supercritical temperatures, the vapor pressure exists only in the subcritical region. In the literature, Henry's law constant is often specified in different units if the concentration of the dissolved gas is not expressed as the mole fraction x_i. Some examples are given in Table 1.

Table 1. Different expressing of Henry's law constant

Constant	Dimension	Concentration
$H_{i,\mathrm{L}}=p_i/x_i$	bar	mole fraction
$H_i^{\mathrm{m}}=p_i/m_i$	bar kg mol^{-1}	molality
$H_i^{\mathrm{c}}=p_i/c_i$	bar m^3 kmol^{-1}	molarity

The following relations are used to recalculate the various dimensions:

$$H_{i,\mathrm{L}}/H_i^{\mathrm{m}}=1000/M_{\mathrm{L}}+\sum_j m_j \tag{24}$$

$$H_{i,\mathrm{L}}/H_i^{\mathrm{c}}=\varrho/M_{\mathrm{L}}+\sum_j c_j\,(1-M_j/M_{\mathrm{L}}) \tag{25}$$

where M is the molar mass in g/mol; m is the molality in mol/kg; c is the molarity in kmol/m^3; and ϱ is the density of the solution in kg/m^3. Indices represent the following: L solvent; i dissolved gaseous component; and j all dissolved components.

At low loading, the concentration-dependent contribution can be neglected and the recalculation can be limited to merely the first term of Equations (24) and (25).

A lot of solubility data have been published in the literature as *solubility coefficients*, defined as the ratio of the amount of gas dissolved at the partial pressure $p_i = 1$ to the amount of solvent. Many solubility coefficients differ in the dimensions used to describe the amounts of gas and solvent or the pressure. Some examples are given in Table 2.

Table 2. Examples of different solubility coefficients

Name	Definition	Dimension
Bunsen	$\alpha_i = V^0{}_i/V_{\mathrm{L}}p_i$	m^3 m^{-3} atm^{-1}
Ostwald	$\beta_i = V_i/V_{\mathrm{L}}\,p_i$	m^3 m^{-3} atm^{-1}
SI	$\lambda_i = n_i/m_{\mathrm{L}}p_i$	mol kg^{-1} bar^{-1}

∗ Conversion factor: 1 atm = 101.325 kPa = 1.013 bar.

In the Bunsen solubility coefficient, the gas volume is given at standard conditions (0 °C and 1 atm); in the Ostwald coefficient, at the measuring temperature. The value m_{L} designates the solvent mass.

A review of the old solubility coefficients with appropriate conversion factors can be found in [11]. Because Henry's law constants are defined in terms of mole fraction and the solubility coefficients in terms of mass ratio, the conversion of solubility coefficients to Henry's law constants depends on the loading or on the partial pressure:

$$H_{i,\mathrm{L}}=\mathrm{factor}/x_{\mathrm{L}}=\mathrm{factor}+p_i \tag{26}$$

where $x_{\mathrm{L}}=1-\sum_i x_i=\mathrm{solvent\,mole\,fraction}$. Factors for converting the most common solubility coefficients to Henry's law constants are listed in Table 3. At low gas loading, $\sum x_i \to 0$, and $x_{\mathrm{L}} \to 1$ or $p_i \to 0$, so that the conversion is independent of the concentration of dissolved gas.

Table 3. Factors for converting solubility coefficients to Henry's law constants

Solubility coefficient	Factor ∗
α_i Bunsen	$1.01325\ v_i^0\,\varrho_{\mathrm{L}}/M_{\mathrm{L}}\ \alpha_i$
β_i Ostwald	$T v^0{}_i\,\varrho_{\mathrm{L}}/269.58\,M_{\mathrm{L}}\ \beta_i$
λ_i SI	$1000/\mathrm{M}_{\mathrm{L}}\ \lambda_i$

∗ $H_{i\ \mathrm{L}}$ is the Henry's law constant of gas i in solvent L in bar; v_i^0 is the molar volume of gas i under standard conditions (0 °C and 101.35 kPa) in m^3/kmol; ϱ_{L} is the density of gas-free solvent in kg/m^3; and T is the temperature in K.

In the design of natural gas and petroleum refineries, the so-called K value

$$K_i=y_i/x_i \tag{27}$$

is often used for the equilibrium of gas solubility. The K value is particularly useful for representing and calculating the solubility equilibria of hydrocarbons (e.g., methane or ethane) in petroleum or gasoline fractions. In these chemically related materials the liquid phase behaves ideally (Raoult's law holds) so that the K values do not depend on the composition of the solvent but only on the temperature and total pressure. The Henry's law constant of component i is calculated from the K value and the pressure

$$H_i=K_i p \tag{28}$$

For an ideal liquid phase, the K values and Henry's law constants are independent of the solvent so the index $_{\mathrm{L}}$ is omitted. Solubility data of gases in liquids, as well as overviews of published solubility equilibria, can be found in [1], [2], [4], [11], and [12].

The IUPAC Solubility Data Series publishes critically selected measured values of gas solubilities [13]; 100 volumes are planned in all.

Many of the published solubility equilibria are stored in data banks [e.g., the Dortmund Data

Bank (DDB), the Berlin Thermodynamic Data Bank (BDBT)] or in Dechema Data Series; they have been published in part or can be accessed via commercial data markets.

A data reduction by the G^E model was illustrated in Section 1.3 for the systems carbon dioxide – methanol and hydrogen sulfide – *N*-methylpyrrolidone. The systems were correlated by using the Peng – Robinson or the Redlich – Kwong – Soave equation of state with the temperature-dependent binary interaction parameters determined by fitting experimental data [14], [15], too.

To represent the solubility of gases in water, in concentrated aqueous solutions of electrolytes, and in hydrocarbons, the hard-sphere model and the Lennard – Jones potential 6 – 12 are used with the dipole – dipole and dipole – induced dipole contributions as the intermolecular interactions [16]. An overview of the older models appears in [11].

1.5. Chemical Absorption

Chemical absorption differs from physical absorption mainly in the higher enthalpy of absorption and the nonlinearity of the absorption isotherms. The high absorption enthalpy is due to chemical reactions of the absorbed gases in the solvents. This is also the reason for the greater temperature dependence of chemical solubility (see Section 1.6). The enthalpy of chemical absorption decreases much more rapidly with increased loading than the enthalpy of physical absorption. Especially after consumption of the chemical capacity (e.g., if amines in the solvent are neutralized by the absorbed acid gases), the chemical enthalpy of absorption decreases precipitously, approaching the physical absorption enthalpy.

The chemical absorption isotherm is nonlinear and Henry's law does not hold. At low loading, the relation $\Delta p/\Delta(\text{load})$ of the dissolved gas increases with increasing loading.

Several isotherms have been proposed for quantitative representation of chemical solubility equilibria; however, they do not have general validity but describe only certain systems. The most important ones are listed in the following material.

Carbon Dioxide in Alkali Carbonate – Bicarbonate. An absorption isotherm for carbon dioxide in an aqueous solution of alkali carbonate – bicarbonate was derived by MacCoy [17] as early as 1903 from the mass action law of the following reactions:

Reaction	Equilibrium	
$CO_2(g) \rightleftharpoons CO_2(l)$	$p(CO_2) = H_c[CO_2]$	(29)
$CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+$	$[CO_2]K_b = [HCO_3^-][H^+]$	(30)
$HCO_3^- \rightleftharpoons CO_3^{2-} + H^+$	$[HCO_3^-]K_k = [CO_3^{2-}][H^+]$	(31)

The formulas in square brackets denote the concentration of the reaction partners; H_c is Henry's law constant for carbon dioxide in water; and K_b and K_k are the dissociation constants of bicarbonate and carbonate, respectively. Thus, from Equations (29) – (31)

$$p(CO_2) = \frac{H_c K_k \left[HCO_3^-\right]^2}{K_b \left[CO_3^{2-}\right]} \tag{32}$$

The concentration of alkali A (alkalinity) follows from the condition of electroneutrality

$$A = \left[HCO_3^-\right] + 2\left[CO_3^{2-}\right] \tag{33}$$

If a specific loading is introduced,

$$X_c = \left[HCO_3^-\right]/A \tag{34}$$

from Equations (32) – (34) follows,

$$p(CO_2) = \frac{H_c K_k 2AX_c^2}{K_b(1-X_c)} = \frac{1}{k} \cdot \frac{2AX_c^2}{1-X_c} \tag{35}$$

The new equilibrium constant k combines all previous constants; like Henry's law constant and the dissociation constant, it is temperature dependent. This temperature dependence is represented by the following empirical formula in the temperature range from 0 to 190 °C [11]:

$$\log k = 4990/(558+t) - 6.265 \tag{36}$$

The constant k is calculated in kmol m^{-3} bar^{-1} if the temperature t is in degrees Celsius. The absorption isotherm (Eq. 35) shows that the partial pressure of carbon dioxide does not grow linear at low loading but with the square of the loading X_c, if $X_c \ll 1$.

The solubility of CO_2 in cold potassium carbonate can be calculated from the following equation [18]:

$$p\,(CO_2) = \frac{0.0338 A^{1.29} X_c^2}{(150-t)\,\lambda_c\,(1-X_c)} \tag{37}$$

which is valid for $0 < t < 40\,°C$ and for $1 < A < 2$ kmol/m^3. The solubility of carbon dioxide in sodium carbonate can be calculated from a similar formula [19]

$$p\,(CO_2) = \frac{0.1015 A^{1.29} X_c^2}{(185-t)\,\lambda_c\,(1-X_c)} \tag{38}$$

which is valid for $18 < t < 65\,°C$ and for $0.5 < A < 2$ kmol/m^3. The solubility constant λ_c in Equations (37) and (38) is calculated as follows:

$$\log\lambda_c = 169/\,(94-t) - 2.89 \tag{39}$$

An empirical formula for CO_2 pressure (atm) over carbonate solution using the relationship molarity $m_a = 2A$ is given by the equation of Astarita et al. (Eq. 40) [71]:

$$p\,(CO_2) = 1.95 \times 10^9 m_a^{0.4} \exp\,(-8160/T)\; X_c^2/\,(1-X_c) \tag{40}$$

In Equations (30)–(40), $p(CO_2)$ is the equilibrium pressure of carbon dioxide in bar, A is the concentration of alkali (alkalinity) in kmol/m^3; X_c is the carbon dioxide loading ($X_c = [HCO_3^-]/A$), t is the temperature in °C; and λ_c is the solubility constant of carbon dioxide in water in kmol m^{-3} bar^{-1}.

In practice, the absorption of carbon dioxide by hot potassium carbonate solution (Hot-Pot of Benfield) is applied widely. Sodium carbonate and cold potassium carbonate are no longer used industrially.

The solubility equilibria of carbon dioxide in a potassium carbonate solution with additives (KH_2AsO_3, KH_2BO_3, K_2SeO_3, $KHTeO_4$, K_2HPO_4), which serve as activators to accelerate the rate of absorption of carbon dioxide, are described in [20].

Sulfur Dioxide in Alkali Sulfite–Bisulfite. By using Equations (29)–(33), with SO_2, HSO_3^-, and SO_3^{2-} replacing CO_2, HCO_3^-, and CO_3^{2-} a formally similar isotherm can be derived for the absorption of sulfur dioxide [21], [22]. The definition of loading, however, differs from that in Equation (34),

$$S_s = [HSO_3^-] + [SO_3^{2-}] \text{ so that}$$
$$[HSO_3^-] = (2\,S_s - A) \text{ and } [SO_3^{2-}] = (A - S_s) \tag{41}$$

are used for the bisulfite and sulfite concentrations, respectively. The partial pressure of sulfur dioxide is then

$$p\,(SO_2) = F\,(T\;)\,(2\,S_s - A)^2/(A - S_s) \tag{42}$$

The temperature-dependent Henry's law and dissociation constants are collected in the function $F\,(T)$. The following empirical formulas for $F\,(T)$ have been proposed for three bases [21], [22]:

Sodium hydroxide	$\log F\,(T\,) = 1.644 - 1987/T$
Methylamine	$\log F\,(T\,) = 2.515 - 2308/T$
Ammonia	$\log F\,(T\,) = 2.990 - 2368/T$

These formulas are valid for $308 < T < 363\,K$ and for the following alkalinities A in mol per 100 mol H_2O:

Sodium hydroxide	$4.0 < A < 7.8$
Methylamine	$7.3 < A < 22.0$
Ammonia	$5.8 < A < 22.4$

The partial pressure of sulfur dioxide is calculated in bar if the loading S_s is expressed in moles per hundred moles of water.

Hydrogen Sulfide and Carbon Dioxide in Alkali Carbonate–Bicarbonate. By the absorption of hydrogen sulfide in aqueous solutions of alkali carbonate–bicarbonate, the following reactions and equilibria are taken into account:

Reaction	Equilibrium	
$H_2S(g) \rightleftharpoons H_2S(l)$	$p(H_2S) = H_s[H_2S]$	(43)
$H_2S \rightleftharpoons H^+ + HS^-$	$K_h[H_2S] = [H^+]\,[HS^-]$	(44)

H_s is Henry's law constant and K_h is the dissociation constant of hydrogen sulfide. From Equations (31), (43), and (44), the partial pressure of hydrogen sulfide is

$$p\,(H_2S) = \frac{H_s K_k\,[HS^-]\,\left[HCO_3^-\right]}{K_h\,\left[CO_3^{2-}\right]} \tag{45}$$

Analogous to Equation (34), the hydrogen sulfide loading X_s is defined as

$$X_s = [HS^-]/A \quad (46)$$

and, from electroneutrality,

$$A = [HS^-] + [HCO_3^-] + 2[CO_3^{2-}] \quad (47)$$

By substitution in Equation (45), the partial pressure of hydrogen sulfide is obtained:

$$p(H_2S) = \frac{H_s K_k 2AX_sX_c}{K_h(1-X_s-X_c)} = \frac{1}{k'}\frac{2AX_sX_c}{(1-X_s-X_c)} \quad (48)$$

All previous constants are combined in the new constant k'. The following empirical formula has been proposed [23] for its temperature dependence:

$$\log k' = -5.81488 + 895.3/T \quad (49)$$

The constant k' is calculated in moles per kilogram and pascal if the temperature T is expressed in kelvin. Absorption isotherms (Eqs. 45 and 48, respectively) show that the partial pressure of hydrogen sulfide increases in direct proportion to its loading X_s. However, during the absorption of 1 mol of H_2S 1 mol H^+ and 1 mol HS^- are generated. By the reversal of Equation (31) 1 mol bicarbonate is formed by the reaction of 1 mol of H^+-ions while 1 mol of carbonate is consumed, so that the partial pressure of H_2S increases more rapidly than the loading.

Many experimental solubility data of hydrogen sulfide and carbon dioxide in aqueous potassium carbonate solution can be found in [24] and [25]. The design of carbon dioxide and hydrogen sulfide absorption with hot potassium carbonate can be calculated with the aid of a published simulation program written in FORTRAN [26].

Equilibria of Carbon Dioxide and Hydrogen Sulfide in Aqueous Ammonia. A model of the solubility equilibria of carbon dioxide and hydrogen sulfide in aqueous ammonia solution is based on the following reactions and equilibria: deprotonization of ammonium ion and reaction of carbamate ion with water [27].

Reaction	Equilibrium	
$NH_4^+ \rightleftharpoons NH_3 + H^+$	$K_a[NH_4^+] = [NH_3][H^+]$	(50)
$NH_2COO^- + H_2O \rightleftharpoons NH_3 + HCO_3^-$		
Carbamate	$K_c[NH_2COO^-] = [NH_3][HCO_3^-]$	(51)

as well as the equilibria for bicarbonate (Eq. 30), carbonate (Eq. 31), and hydrogen sulfide (Eq. 44). In addition, Henry's law (Eqs. 29 and 43) was taken into account. The mathematical description of the system is based on the material balance of ammonia, carbon dioxide, and hydrogen sulfide, as well as on electroneutrality. The equations can be solved by an approximation method, and the equilibria can thus be calculated. A better representation of solubility equilibria over a broad range of concentration is achieved by introducing activity coefficients. Remarkable progress was made during the 1970 s in calculating activity coefficients of electrolytes [28], [29].

A calculation of activity coefficients by the semiempirical method of Bromley and Pitzer, by using the TIDES program, successfully reproduces experimental solubility data of carbon dioxide in concentrated ammonia solutions [30]. An additional program, DELTAS, is available for calculating equilibria in a multicomponent system containing ammonia, phenol, carbon dioxide, hydrogen sulfide, hydrogen cyanide, sulfur dioxide, and water; it was used for calculating solubility equilibria in sour water strippers (i.e., desorbers for the removal of hydrogen sulfide, carbon dioxide, hydrogen cyanide, and ammonia from waste water).

This model was checked experimentally by measuring hydrogen sulfide – ammonia solubilities at extremely high ammonia concentrations; it reproduced the total pressure with less than ± 10 % error up to about 30 mol/kg [31]. This error becomes larger with further increasing concentration.

The fugacity of the vapor phase has been calculated according to the Peng – Robinson equation of state, and the effect of water vapor pressure on solubility equilibria at temperatures above 150 °C is demonstrated in [32]. Commercial simulation programs also make use of other models, e.g., the Chen model in Aspen Plus.

The vapor – liquid equilibria of ammonia and hydrogen sulfide in aqueous solutions are given by Newman [33] in the form of charts. They can be used for fast estimations without computer, but a trial-and-error method is required.

Experimental data on the simultaneous solubility of ammonia and carbon dioxide in concentrated aqueous solutions containing dissolved salts are reported by Maurer et al. [34]; for solutions containing sodium sulfate, see [35]. A data-correlation model treats the gas phase by

means of second virial coefficients, and the activity coefficients in the liquid are calculated by a modified Pitzer method for the excess Gibbs energy of an aqueous electrolyte solution. Selected binary and some ternary interaction parameters were fitted to the experimental data.

Carbon Dioxide – Hydrogen Sulfide in Alkanolamine. A well-known method of KENT and EISENBERG for representing solubility equilibria of carbon dioxide and hydrogen sulfide in aqueous alkanolamine solutions is based on nine reactions with their accompanying equilibrium constants [36]:

Reaction	Equilibrium	
$RRNH_2^+ \rightleftharpoons H^+ + RRNH$	$K_a[RRNH_2^+] = [H^+][RRNH]$	(52)
$RRNCOO^- + H_2O \rightleftharpoons RRNH + HCO_3^-$	$K_c[RRNCOO^-] = [RRNH][HCO_3^-]$	(53)
$H_2O \rightleftharpoons H^+ + OH^-$	$K_w = [H^+][OH^-]$	(54)

as well as Equations (29) – (31) and (40) – (41).

Together with the mass balance of amine, carbon dioxide, and hydrogen sulfide, as well as electroneutrality in the solution, a system of equations is obtained which can be solved by an approximation method. No explicit formula for the isotherm of the entire system of equations is known, but the equations can be solved by computer and the solubility equilibria calculated. The numerical values needed to calculate the temperature-dependent Henry's law constants and the dissociation constants of carbonate, bicarbonate and carbamate, sulfide and hydrogen sulfide, as well as two alkanolamines [monoethanolamine (MEA) and diethanolamine (DEA)], are given in [36].

With the aid of this model, nomograms can also be calculated [37], by means of which the simultaneous solubility equilibria of carbon dioxide and hydrogen sulfide in MEA or DEA can be determined even without a powerful computer. Significant deviations from the model, which occur at high loading, are corrected by using empirical factors.

Subprograms are available for calculating solubility equilibria by use of professional simulation programs, for example, an "Amine Data Package" for PROCESS. Similar subprograms are offered for ASPEN, SOFTEC, and ChemShare. The simulation programs TSWEET and AMSIM (Amine Gas Treating Plant Simulator) are also available [38], [39].

In a simplified solubility model for a single gas (CO_2 or H_2S) reacting with an amine in stoichiometric ratios of 1 : 1 and 1 : 2, the effect of amine concentration is described by an activity coefficient of the solvent [40]. Numerical values of Henry's law and reaction constants are given for three nonaqueous solvents and their mixtures.

A formally similar model has been used for two acid gases [41]. In this case, only a single reaction is considered per gas: the dissociation of H_2S to HS^- and H^+ and the conversion of carbon dioxide to carbamate. In both solubility models, a system of equations must be solved by an approximation method.

To represent the solubility of carbon dioxide in MEA solutions explicitly [42], [43], an isotherm has been derived from the following reaction

$$CO_2 + 2\,RNH_2 \rightleftharpoons RNHCOO^- + RNH_3^+ \tag{55}$$

From the equilibrium constant of this reaction and the amine balance, it folllows that

$$p\,(CO_2) = A\,[X_c/\,(1 - 2X_c)]^2 \exp\,(B) \tag{56}$$

The dependence of parameters A and B on the temperature T and specific loading X_c is represented by empirical equations

$$\ln A = -3.70 - 4.83X_c \tag{57}$$

$$B = \left(9.71 + 8.18X_c - 25.2X_c^2\right)(3.0 - 1000/T) \tag{58}$$

which can be used in the temperature range 0 – 140 °C, at specific loadings $X_c < 0.45$ mol/mol and MEA concentrations from 0.5 to 9.5 kmol/m^3. Another explicit isotherm of carbon dioxide is derived in [44]. The derivation is based on the assumption that the carbonate concentration in an alkanolamine solution is so low it can be neglected in the mass balance. The solution of the equations for physical solubility (Eq. 29), bicarbonate (Eq. 30), and carbamate (Eq. 53), and for the mass balance of amine and carbon dioxide as well as electroneutrality (without H^+ and OH^-),

$$A = [RRNH] + \left[RRNCOO^-\right] + \left[RRNH_2^+\right] \tag{59}$$

$$AX_c = \left[RRNCOO^-\right] + \left[HCO_3^-\right] \tag{60}$$

$$\left[\mathrm{RRNH_2^+}\right] = \left[\mathrm{RRNCOO^-}\right] + \left[\mathrm{HCO_3^-}\right] \tag{61}$$

leads to the following isotherm

$$p\left(\mathrm{CO_2}\right) = \frac{H_\mathrm{c} K_\mathrm{a} A}{K_\mathrm{b}} \cdot \frac{X_\mathrm{c}\left[X_\mathrm{c} - F\left(X_\mathrm{c}\right)\right]}{1 - X_\mathrm{c} - F\left(X_\mathrm{c}\right)} \tag{62}$$

The function $F\left(X_\mathrm{c}\right)$ can be replaced by

$$F\left(X_\mathrm{c}\right) = Sa - \left[Sa^2 - X_\mathrm{c}\left(1 - X_\mathrm{c}\right)\right]^{1/2} \tag{63}$$

where Sa is a factor proposed by SARTORI and SAVAGE which is defined as

$$Sa = \left(1 + K_\mathrm{c}/A\right)/2 \tag{64}$$

Equation (62) shows the effect of carbamate formation on the solubility isotherm. Carbamates can be formed only from primary and secondary amines. Tertiary amines do not form carbamates, and sterically hindered amines do so to only a minor extent.

For the simultaneous solubility equilibria of carbon dioxide and hydrogen sulfide in aqueous MDEA solution, absorption isotherms have been derived from the equilibria of bicarbonate (Eq. 30), hydrogen sulfide (Eq. 44), and amine hydrolysis (Eq. 52), as well as from Henry's law constant, electroneutrality, and amine balance [45].

$$p\left(\mathrm{CO_2}\right) = \frac{H_\mathrm{c} K_\mathrm{a} A}{K_\mathrm{b}} \frac{X_\mathrm{c}\left(X_\mathrm{c} + X_\mathrm{s}\right)}{1 - X_\mathrm{c} - X_\mathrm{s}} \tag{65}$$

$$p\left(\mathrm{H_2S}\right) = \frac{H_\mathrm{s} K_\mathrm{a} A}{K_\mathrm{h}} \frac{X_\mathrm{s}\left(X_\mathrm{c} + X_\mathrm{s}\right)}{\left(1 - X_\mathrm{c} - X_\mathrm{s}\right)} \tag{66}$$

OTTO et al. and MATHER et al. have published extended experimental data on solubility equilibria for carbon dioxide and hydrogen sulfide in aqueous solutions of alkanolamine (see Table 4).

Table 4. Solubility equilibria of carbon dioxide and hydrogen sulfide in aqueous alkanolamine solutions

Amine *	Gas	Reference
DEA	$H_2S + CO_2$	[46], [47]
DIPA	H_2S, CO_2	[48]
DIPA	$H_2S + CO_2$	[49]
DGA	H_2S, CO_2	[50]
MEA	$H_2S + CO_2$	[51]
MDEA	H_2S, CO_2	[52], [55], [56]
MEA + MDEA	CO_2	[57], [58]
DEA	H_2S, CO_2	[41], [54]
AMP	H_2S, CO_2	[59]
AMP	$H_2S + CO_2$	[60]
TEA	$H_2S + CO_2$	[53]

* AMP = 2-amino-2-methyl-1-propanol, DEA = diethanolamine, DGA = diglycolamine, DIPA = diisopropanolamine, MDEA = methyl diethanolamine, MEA = monoethanol amine, and TEA = triethanolamine

A model of vapor – liquid equilibria for aqueous solutions of acid gases in alkanolamines in which the activity coefficients are represented by the electrolyte NRTL equation was published by AUGSTEN et al. [61], [62]. The NRTL molecule – ion pair binary interaction parameters are fitted to experimental data with the data-regression system of the Aspen Plus process simulator.

A correlation of the solubility of CO_2 and H_2S in a mixed alkanolamine solutions by using the Pitzer electrolyte model and the Margules expansion for excess Gibbs energy was published by LI and MATHER [63], [64]. One binary molecule – molecule, as well as one binary and two ternary ion – moleule interaction parameters, are fitted to experimental data.

A new absorption isotherm for the solubility of acid gases in basic solutions was published in 1993 by SCHLAUER [65]. The chemistry of the reactions is established by the kinetics in Chapter 2.5. With the amine R_2NH as the base B, $R_2N^+HCO_2^-$ as the zwitterion, and $R_2NH_2^+$ as the protonated base, the equilibria of Equations (150) and (151) are given by Equations (67) and (68).

$$K_\mathrm{z}\left[\mathrm{R_2NH}\right]\left[\mathrm{CO_2}\right] = \left[\mathrm{R_2N^+HCO_2^-}\right] \tag{67}$$

$$K_\mathrm{d}\left[\mathrm{R_2N^+HCO_2^-}\right]\left[\mathrm{R_2NH}\right] = \left[\mathrm{R_2NCOO^-}\right]\left[\mathrm{R_2NH_2^+}\right] \tag{68}$$

with reaction constants K_z and K_d for the generation of the zwitterion and its decomposition to the carbamate R_2NCOO^-, respectively. Such reactions generally describe stoichiometric ratios of acid gas to amine of 1:1 and 1:2.

$$A = \left[\mathrm{R_2N^+HCO_2^-}\right] + \left[\mathrm{R_2NH}\right] + \left[\mathrm{R_2NCOO^-}\right] + \left[\mathrm{R_2NH_2^+}\right] \tag{69}$$

$$X_\mathrm{c} A = \left[\mathrm{CO_2}\right] + \left[\mathrm{R_2N^+HCO_2^-}\right] + \left[\mathrm{R_2NCOO^-}\right] \tag{70}$$

$$\left[\mathrm{R_2NCOO^-}\right] = \left[\mathrm{R_2NH_2^+}\right] \tag{71}$$

Eq. (29):

$$p_\mathrm{c} = H_\mathrm{c}\left[\mathrm{CO_2}\right]$$

Equations (67) and (68), the mass balances of the base (Eq. 69) and of the acid gas (Eq. 70), the electroneutrality condition (Eq. 71), and Henry's law (Eq. 29) can be solved analytically to give

$$X_c = \frac{p_c}{H_c A} + \frac{p_c K_z/H_c + (p_c K_d K_z/H_c)^{1/2}}{1 + p_c K_z/H_c + 2\,(p_c K_d K_z/H_c)^{1/2}} \quad (72)$$

$$X_c = \frac{p_c}{H_c A} + \frac{p_c C_c + (p_c B_c)^{1/2}}{1 + p_c C_c + 2\,(p_c B_c)^{1/2}} \quad (73)$$

where

$$C_c = K_z/H_c \text{ and } B_c = K_d K_z/H_c \quad (74)$$

whereby the parameters H_c, C_c, and B_c are fitted to the experimental data. The isotherm also applies to the solubility of other sour gases in alkaline solvents, for example, H_2S in aqueous MDEA (Fig. 3). The H_2S fugacity was calculated from the experimental partial pressure by a truncated virial equation of state, and the second virial coefficients were calculated according to PRAUSNITZ et al. [2]

Figure 3. Comparison of predicted and experimental equilibrium data for H_2S in 1 M aqueous MDEA

The isotherm can be expanded to the simultaneous solubility of more sour gases (Eq. 75).

$$X_i = \frac{p_i}{H_i A} + \frac{p_i C_i + p_i B_i / \left(\sum_j p_j B_j\right)^{1/2}}{1 + \sum_j p_j C_j + 2\left(\sum_j p_j B_j\right)^{1/2}} \quad (75)$$

Experimental solubility data of the single gases carbon dioxide and hydrogen sulfide in aqueous solutions of MDEA were correlated by MAURER et al. [55] with a model already described for aqueous solutions of ammonia. Selected binary parameters and one ternary interaction parameter were fitted to the experimental data.

1.6. Enthalpy and Absorption Equilibrium

The temperature dependence of the fugacity f_i of a dissolved component i is related to the molar enthalpy of absorption $\Delta H_i^{\mathrm{Abs}}$ of this component by the Clausius – Clapeyron equation

$$\delta \ln f_i/\delta T = -\,\Delta H_i^{\mathrm{Abs}}/RT^2 \Delta z_i \quad (76)$$

where Δz_i is the difference between the compressibility factors of the vapor and liquid phases

$$\Delta z_i = z_i^{\mathrm{G}} - z_i^{\mathrm{L}} = \left(v_i^{\mathrm{G}} - v_i^{\mathrm{L}}\right) p/RT \quad (77)$$

For $z_i^{\mathrm{G}} \approx 1$ in the vapor phase and $z_i^{\mathrm{L}} \ll 1$ in the liquid phase follows: $\Delta z_i \approx 1, f_i \approx p_i$,

$$\Delta H_i^{\mathrm{Abs}} = R\,[\delta \ln p_i/\delta\,(1/T)]_x \quad (78)$$

Equation (78) is used to calculate the *differential enthalpy of absorption* at a loading x_i from known solubility equilibria. An *average enthalpy of absorption* for a loading from x_i (1) to x_i (2) is determined by the appropriate integration

$$\Delta H_i^{\mathrm{Abs}} = \int_{x(1)}^{x(2)} \Delta H_i^{\mathrm{Abs}} \mathrm{d}x_i / [x_i\,(2) - x_i\,(1)] \quad (79)$$

The enthalpy of absorption can be calculated by using UNIQUAC [2] or UNIFAC [66]. The temperature dependence of Henry's law constant $H_{i,\,\mathrm{L}}$ is determined from Equations (21) and (78):

$$\delta \ln H_{i,\mathrm{L}}/\delta\,(1/T) = \Delta H_i^{\mathrm{Abs}}/R \quad (80)$$

The temperature dependence of Henry's law constants can be estimated roughly by using the following formula [9]:

$$H_{i,\mathrm{L}} = \gamma_{i,\mathrm{L}}^{\infty} f_i^0 \tag{81}$$

where $\gamma_{i,\mathrm{L}}^{\infty}$ is the activity coefficient of gas component i in the solvent L at infinite dilution and f_i^0 is the standard fugacity. The standard fugacity is independent of the solvent, and its generalized temperature dependence is given by

$$\ln\left(f_i^0/p_{\mathrm{c},i}\right) = 7.224 - 7.534/T_{\mathrm{r},i} - 2.598 \ln T_{\mathrm{r},i} \tag{82}$$

for a range of temperatures $0.6 < T_{\mathrm{r},i} < 16$. The activity coefficient at infinite dilution $\gamma_{i,\mathrm{L}}^{\infty}$ is specific for each pair (gas component i and solvent L) but only weakly dependent on the temperature.

At low temperatures, Henry's law constant increases with increasing temperature until a maximum at $T_{\mathrm{r},i} = 2.8$ is reached. At higher temperatures Henry's law constant decreases slightly, i.e., the solubility again increases.

The enthalpy of absorption increases steadily with increasing temperature (i.e., it decreases in absolute value) and reaches zero at $T_{\mathrm{r},i} = 2.8$. At lower temperatures, heat is liberated during absorption; at higher temperatures, it is consumed. In *chemical absorption* the enthalpy of absorption is strongly dependent on loading [52]. Once the chemical capacity has been saturated, the absorption enthalpy drops substantially.

The temperature dependence of the solubility equilibria and the enthalpy of absorption is of paramount importance in designing an absorption installation. In the absorber, the gas component to be washed out must be highly soluble. In the regenerator where the absorbed gas component from the solvent is removed, the solubility must be as low as possible. The strong increase in solubility at low temperatures is utilized particularly in physical absorption processes, the absorber being operated at as low a temperature as possible and the regenerator at a high temperature. Because the enthalpy of absorption becomes negative and, in absolute terms, always increases with decreasing temperature, provision must be made to remove the liberated heat of absorption from the absorber to improve the efficiency of the process. To do so, solvent is removed from the absorber, cooled, expanded, and then recirculated to the absorber.

To obtain as pure a treated gas as possible, the regenerated solvent is cooled to a very low temperature before it is brought to the absorber head. The lowest temperature is obtained by adiabatic expansion of the loaded solvent (possibly under vacuum).

In processes involving chemical absorption, reaction kinetics limit the use of low temperatures in an absorber. Although the partial pressure of a dissolved component drops as the temperature decreases, this fact cannot be used to advantage in an industrial absorber because the rates of chemical reaction are retarded by low temperatures to such an extent that mass transfer is hindered and a long residence time (i.e., a larger absorber) is required. Reaction kinetics of chemical absorption and the use of kinetic effects are dealt with in Chapter 2.

2. Mass Transfer

A comprehensive treatment of mass transfer phenomena is given elsewhere (→ Transport Phenomena).

2.1. Introduction

This chapter deals with mass transfer during absorption occurring in a gas – liquid system not in equilibrium. The nonequilibrium produces concentration gradients at the interface and mass transfer across this boundary, which tends to equilibrate the system.

During absorption or desorption, the absorbed component cannot spread spontaneously over the total volume of a phase. In the gas phase, mass transfer during absorption is hindered by the gaseous components that are not absorbed and remain as purified gas. During desorption, it is hindered by the stripping gas or stripping steam. In the liquid phase, mass transfer is hindered by the solvent.

Mass transfer of the absorbed components near the interface occurs mainly by diffusion and, in the bulk of the phase, mainly by turbulence. At equilibrium, mass transfer across the interface is equal in both directions so that no concentration gradient is established near the phase boundary. This chapter deals only with mass transfer that occurs before equilibrium has been established between the two phases, not with mass transfer at equilibrium.

2.2. Mass Transfer Coefficients

Mass transfer across the interface of a component to be absorbed is described quantitatively by the mass transfer coefficients. The definition of these coefficients is based on two assumptions:

1) At the phase boundary the gas and liquid phases are at equilibrium. Significant deviations from equilibrium at the interface occur only if mass transfer is extremely rapid.
2) Mass transfer is proportional to the difference between the concentration in the bulk of the phase and the concentration at the interface.

In the stationary state, mass transfer is equal on both sides of the interface so that

$$N_{\mathrm{A}}=k_{\mathrm{G}}\left(y^{\mathrm{b}}-y^{\mathrm{i}}\right)=k_{\mathrm{L}}\left(x^{\mathrm{i}}-x^{\mathrm{b}}\right) \tag{83}$$

The mass transfer rate N_{A} is the number of moles of an absorbed component A being transferred across a unit area of the interface per time unit; y^{b} and x^{b} are the mole fractions of component A in the bulk of the gas and liquid phases; y^{i} and x^{i} are the mole fractions at the interface. The proportionality constants k_{G} and k_{L} are the mass transfer coefficients in the gas and liquid phase, respectively. The mole fractions at the interface can be calculated from known mass transfer coefficients and solubility equilibria by using the following approximation method:

1) Mole fractions $x*$ and $y*$ are calculated which are in equilibrium with mole fractions y^{b} and x^{b} in the bulk of the other phases

$$y^{*}=F\left(x^{\mathrm{b}}\right) \text{ and } y^{\mathrm{b}}=F\left(x^{*}\right) \tag{84}$$

where $F\left(x^{\mathrm{b}}\right)$ and $F\left(x*\right)$ are the solubility equilibrium relationships.

2) An intermediate value C is calculated

$$C=\frac{k_{\mathrm{G}}\left(y^{\mathrm{b}}-y^{*}\right)}{k_{\mathrm{L}}\left(x^{*}-x^{\mathrm{b}}\right)} \tag{85}$$

3) As a first approximation, the equilibrium concentration at the interface is

$$y_1=\left(Cy^{\mathrm{b}}+y^{*}\right)/(1+C) \tag{86}$$

$$x_1=x^{\mathrm{b}}+\left(y^{\mathrm{b}}-y_1\right)k_{\mathrm{G}}/k_{\mathrm{L}} \tag{87}$$

4) The question of whether these values satisfy the solubility equilbrium relation

$$y_1^{*}=F\left(x_1\right) \tag{88}$$

by meeting the following condition

$$Abs\left[y_1^{*}-y_1\right]<\mathrm{Abs}\left[y_1-y^{\mathrm{b}}\right]/100 \tag{89}$$

must be checked. If condition (89) is met, the relative deviation is less than 1 %. If not, the calculation is repeated beginning with step 1, but the new values x_1 and y_1 in Equation (87) are used in place of the mole fractions x^{b} and y^{b}. Figure 4 shows that this approximation method converges rapidly, even if the absorption equilibrium is strongly nonlinear.

Figure 4. Prediction of the concentration at the interface: graphical demonstration of the approximation

If the absorption equilibrium in the concentration region employed can be represented by a straight line

$$y=n+mx \quad (n,m=\text{ const.}) \tag{90}$$

the mass transfer is also proportional to the difference between the concentration in the bulk of one phase and the equilibrium value of the other phase

$$N_{\mathrm{A}}=K_{\mathrm{G}}\left(y^{\mathrm{b}}-y^{*}\right)=K_{\mathrm{L}}\left(x^{*}-x^{\mathrm{b}}\right) \tag{91}$$

These proportionality constants K_{G} and K_{L} are the overall mass transfer coefficients in the gas and liquid phase, respectively. For recalculation,

$$1/K_L = 1/k_L + 1/mk_G \tag{92}$$

$$1/K_G = 1/k_G + m/k_L \tag{93}$$

$$K_L = mK_G \tag{94}$$

The inverse of the mass transfer coefficients can be considered the resistance to mass transfer, and the overall resistance consists of the resistance in the gas and liquid phases. If the resistance is substantially greater in one phase than in the other, it is called a one-sided resistance. For one-sided resistance in the gas phase,

$$k_L \gg mk_G \;\; x^i \to x^b,\; y^i \to y^* \tag{95}$$

If resistance in the liquid phase predominates, analogously,

$$k_L \ll mk_G \;\; x^i \to x^*,\; y^i \to y^b \tag{96}$$

The concentrations at the interface can only be between these extremes (cf. Fig. 4).

$$x^b \le x^i \le x^* \text{ and } y^* \le y^i \le y^b \tag{97}$$

In industrial absorption devices, where the surface of the interface cannot be determined accurately, volume-related mass transfer coefficients are used

$$K_L a, K_G a, k_L a, \text{and } k_G a \tag{98}$$

where a is the unknown surface of the interface per unit volume of the absorption device. For recalculation,

$$1/K_L a = 1/k_L a + 1/mk_G a \tag{99}$$

$$1/K_G a = 1/k_G a + m/k_L a \tag{100}$$

These relationships are especially useful in a physical solubility equilibrium, where a dimensionless Henry's law constant $H_{i,\,L}/p$ or the K value can be substituted for m. The surface a decreases with decreasing liquid flow rate L and with increasing surface tension (Marangoni effect) because streams are formed and the surface of the packing is not completely wetted [74]. The effective phase surface and the mass transfer coefficients has been measured in contact devices [75] for gases with polar and nonpolar liquids as well as with highly viscous hydrocarbons.

Numerical values of mass transfer coefficients $K_G\,a$ in packed columns for several industrially important absorption systems can be found in [67], [73] and [75].

2.3. Effect of Solute Concentration

The relations given in Section 2.2 are valid only for low concentration of the absorbed component A, as long as $x_A \ll 1$ and $y_A \ll 1$. At higher concentration, the mass flow created by diffusion must be taken into account [68]. If two components A and B in a gas film at the interface are considered, a concentration gradient is formed in which

$$N_A = -cD_{AB}\frac{dy_A}{dz} + y_A\,(N_A + N_B) \tag{101}$$

Here, c is the overall concentration of components A and B in the gas phase, z the distance from the interface, and D_{AB} the diffusion constant of component A in the binary gas mixture. In the steady state, the components diffuse in opposite directions so that only the adsorbed component A flows through the gas film; the nonadsorbed component B remains in the gas film. Hence, $N_B = 0$ and from Equation (101),

$$N_A = -\frac{cD_{AB}}{1-y_A}\frac{dy_A}{dz} \tag{102}$$

The mass transfer of component A increases in proportion to the concentration gradient dy_A/dz and to $1/(1-y_A)$, hence with increasing concentration of y_A. From the continuity of mass transfer,

$$\frac{dN_A}{dz} = 0 \text{ then } \frac{d}{dz}\left(\frac{1}{1-y_A}\cdot\frac{dy_A}{dz}\right) = 0 \tag{103}$$

After the first and second integration,

$$[1/(1-y_A)]\,dy_A/dz = C_1 \tag{104}$$

$$-\ln(1-y_A) = zC_1 + C_2 \tag{105}$$

The constants C_1 and C_2 can be calculated from the boundary conditions that exist at the interface and at the boundary between the gas film and the bulk of the gas phase

$$y_A = y_A^i \text{ if } z = 0 \tag{106}$$

$$y_A = y_A^b \text{ if } z = \delta_G \tag{107}$$

where δ_G is the thickness of the gas film or the distance from the interface where the concentration in the gas phase attains the value y_A^b. From Equations (104) – (107),

$$C_2 = -\ln\left(1-y_A^i\right) = -\ln y_B^i \tag{108}$$

$$C_1 = \frac{1}{z}\ln\frac{1-y_A^i}{1-y_A^b} = \frac{1}{z}\ln\frac{y_B^i}{y_B^b} \tag{109}$$

and, finally, Equations (103), (104), and (105)

$$N_A = \frac{cD_{AB}}{\delta_G}\ln\frac{1-y_A^i}{1-y_A^b} = \frac{cD_{AB}}{\delta_G}\ln\frac{y_B^i}{y_B^b} \tag{110}$$

This equation describes the mass transfer at all concentrations of adsorbed component A. At a lower concentration,

$$\ln(1-y_A) \approx -y_A \quad (y_A \to 0) \tag{111}$$

and Equation (110) becomes

$$N_A = \frac{cD_{AB}}{\delta_G}\left(y_A^b - y_A^i\right) \tag{112}$$

By comparison with the definition of N_A (Eq. 83),

$$k_G = cD_{AB}/\delta_G \tag{113}$$

In an ideal gas phase, the concentration c is

$$c = p/RT \tag{114}$$

and the mass transfer coefficient is

$$k_G = pD_{AB}/\delta_G RT \tag{115}$$

which defines the thickness of the gas film δ_G; it is strongly dependent on turbulence in the gas phase. Similar dependencies on concentration apply in the liquid, but as a rule, the concentration of the absorbed component in the liquid phase is low.

2.4. Correlation of Mass Transfer Coefficients

Empirical relationships from dimensionless analysis are used to correlate mass transfer coefficients in the gas phase. One criterion for the *mass transfer coefficient in the gas phase* is the Sherwood number

$$Sh = k_G RT d/pD_{AB} \tag{116}$$

As characteristic length d is usually taken the dimensions of the adsorption column packing, the diameter of the gas channel in a perforated plate, or the space between the bubble cap and the plate. Turbulence in the gas phase is characterized by the Reynolds and Schmidt numbers:

$$Re = G_M d/\mu_G \tag{117}$$

$$Sc = \mu_G/\varrho_G D_{AB} \tag{118}$$

The following relationship has been established from experimental mass transfer data in an absorption unit:

$$Sh = St \cdot Re \cdot Sc = f(Re, Sc) \tag{119}$$

This empirical relation can then be used to scale up absorbers of the same type. The dimensionless Stanton number is defined as

$$St = k_G M_G/G_M \tag{120}$$

The following empirical formula has been proposed for mass transfer in packed columns with Raschig rings and Berl saddles [76]:

$$j_M = St \cdot Sc^{2/3} = 1.195 Re^{-0.36} \tag{121}$$

where j_M is the j factor according to Chilton–Colburn for the modified Reynolds analogy among mass, heat, and impulse transfer. Here, the Reynolds number is modified somewhat to

$$Re = G_M d/\mu_G (1-\varepsilon) \tag{122}$$

where d is the diameter of a sphere having the same surface as a piece of packing and ε is the void fraction of the packing available for gas flow.

In Equations (117)–(122), k_G is the mass transfer coefficient in kmol s^{-1} m^{-2}; G_M is the specific gas flow rate in kg s^{-1} m^{-2}; d is the characteristic length in m; μ_G is the viscosity of the gas phase in kg s^{-1} m^{-1}, ϱ_G is the density of the gas phase in kg/m^3; D_{AB} is the diffusion constant of component A in m^2/s in inert gas B; and M_G is the molar mass of the gas phase $= \sum y_i M_i$ in kg/kmol.

The following empirical formula can be used for mass transfer in bubble-cap tray absorption columns [77]:

$$k_g = 7\left(u^{1/2} D_{AB}/s\right)^{1/2} \tag{123}$$

Here k_g is the mass transfer coefficient in cm/s; u is the gas velocity in cm/s; s is the liquid level on the tray in cm; and D_{AB} is the diffusion coefficient in cm^2/s.

To convert from k_g to k_G (SI units),

$$k_G = k_g/100V \tag{124}$$

or

$$k_G = k_g p/100RT \tag{125}$$

where V is the molar volume of the gas phase in cubic meters per kilomole. Equation (125) applies to an ideal gas phase. The *mass transfer coefficients* k_L *in the liquid phase* for Raschig rings and Berl saddles can be calculated with the following empirical formula [76]; similar correlations also apply to packed columns [78]:

$$St = 25.1 Re^{0.45} \cdot Sc^{0.5} \tag{126}$$

The Stanton, Reynolds, and Schmidt numbers in the liquid are

$$St = k_L M_L / L_M \tag{127}$$

$$Re = L_M d/\mu_L \tag{128}$$

$$Sc = \mu_L / p_L D_{AL} \tag{129}$$

where k_L is the mass transfer coefficient in kmol s^{-1} m^{-2}; M_L the molar mass of liquid in kg/kmol; d the characteristic length in m; D_{AL} the diffusion constant of component A in the liquid phase in m^2/s; ϱ_L the density of liquid phase in kg/m^3; L_M the specific liquid flow rate in kg s^{-1} m^{-2}; and μ_L the viscosity of the liquid phase in kg s^{-1} m^{-1}.

Additional correlations of mass and heat transfer can be found in [79–84].

Another relation holds for the mass transfer of carbon dioxide from a *supersaturated aqueous solution* in a container with a stirrer [85]. As long as no bubbles are formed, mass transfer through the surface of the liquid can be described by the following empirical formula:

$$Sh = 0.322 Re^{0.7} \cdot Sc^{1/3} \tag{130}$$

In this case, the Sherwood, Reynolds, and Schmidt numbers are defined as follows

$$Sh = k_l d / D_{AL} \tag{131}$$

$$Re = d_L^2 n_L \varrho_L / \mu_L \tag{132}$$

$$Sc = \mu_L / \varrho_L D_{AL} \tag{133}$$

where d_L is the stirrer diameter in m; n_L is the rotation rate of the stirrer in s^{-1}; d is the container diameter in m; and k_l is the mass transfer coefficient in m/s.

The mass transfer coefficient k_l is expressed in meters per second and like Equation (83), is defined by the difference in concentrations

$$N_A = k_l \left(c_A^i - c_A^b \right) \tag{134}$$

The concentrations of component A at the interface c_A^i and the bulk of the liquid phase c_A^b, are expressed in $kmol/m^3$.

To convert k_l to k_L (mass transfer coefficient referred to mole fraction)

$$k_l = k_L / M_L \varrho_L \tag{135}$$

is used. In *highly supersaturated solutions*, bubble formation occurs which increases the phase surface and intensifies turbulence. Two regions of spontaneous bubble formation of this type exist which differ in the intensity of bubble formation depending on the supersaturation σ:

$$\sigma = \left(c_A^b - c_A^* \right) / c_A^* \tag{136}$$

where c_A^* is the concentration in equilibrium with the gas phase (bulk). Bubble formation is weak up to critical supersaturation σ_c, and the volume-related mass transfer coefficient in the bulk of the liquid phase is

$$k_l^b a = 6.77 10^{-6} Re^{0.5} \cdot \sigma^{0.78} \tag{137}$$

Once the critical supersaturation has been exceeded and $\sigma > \sigma_c$, bubble formation becomes intense, and the mass transfer coefficient is

$$k_l^b a = 2.45 10^{-6} Re^{0.98} \cdot \sigma^{2.5} \tag{138}$$

For the critical supersaturation σ_c between weak and intense bubble formation, the range of validity is defined as follows:

$$\sigma_c = 1.81 Re^{-0.25} \tag{139}$$

$$2190 < Re < 14000 \tag{140}$$

$$0.038 < \sigma < 0.80 \tag{141}$$

2.5. Mass Transfer and Chemical Reaction

If the absorbed component reacts in the liquid phase and is thus transformed chemically, its mass transfer in the liquid phase is accelerated. If this reaction is irreversible, the absorbed component reacts until its concentration in the liquid phase is practically zero. Thus, for example, in the absorption of carbon dioxide in aqueous potassium hydroxide solution, carbonate (CO_3^{2-}) and traces of bicarbonate (HCO_3^-) can be found in solution, but practically no carbon dioxide as long as an excess of alkali is present. Mass transfer is then independent of loading and proportional to the concentration at the interface c_A^i because the concentration in the bulk of the liquid phase $c_A^b = 0$.

For an irreversible first-order reaction, the mass transfer coefficient in the liquid phase depends on the Hatta number [86]. According to Danckwert's surface renewal theory, the mass transfer coefficient including a reaction of component A with reactant B is calculated according to the following relation [87]:

$$k_l' = \left(k_l^2 + D_{AL} k_{11} c_B^b\right)^{1/2} = k_l \left(1 + Ha^2\right)^{1/2} = k_l E \tag{142}$$

where Ha is a dimensionless Hatta number, E is the enhancement factor, k_{11} is the reaction rate constant, and k_l is the mass transfer coefficient in the liquid phase without a reaction.

$$Ha = \left(D_{AL} k_{11} c_B^b\right)^{1/2} / k_l \tag{143}$$

$$E = \left(1 + Ha^2\right)^{1/2} \tag{144}$$

For large Hatta numbers beginning with $Ha > 3$, the enhancement factor $E \approx Ha$. These parameters describe the contribution of the reaction to mass transfer if a chemical reaction occurs. This equation can also be used for a pseudo-first-order reaction, as long as an excess of B is present. For very rapid reactions, the Hatta number is large and mass transfer is controlled increasingly by the mass transfer coefficient of the gas phase.

The reaction rate constants k_{11} of the most frequently encountered reactions are known, and their temperature dependence is represented according to ARRHENIUS by

$$k_{11} = F \exp\left(-E^A / RT\right) \tag{145}$$

where F is the frequency factor and E^A the activation energy of the reaction; numerical values of some *second-order reactions* are given in Table 5.

Table 5. Frequency factors and activation energies of several second-order reactions

Reaction	ln F, $m^3\,k\,mol^{-1}\,s^{-1}$	E^A, kJ/mol	References
$CO_2 + OH^-$	31.43	55.42	[88], [89]
$CO_2 + H_2O$	26.13	70.98	[89]
$CO_2 + NH_3$	25.63	48.43	[89]
CO_2 + MEA	25.84	41.92	[90]
	25.31	41.20	[91]
CO_2 + MIPA	26.43	43.84	[90]
CO_2 + TEA	24.68	51.46	[91]
CO_2 + MDEA	16.83	37.21	[92]
	18.63	42.48	[93]
	29.80	71.71	[94]
NO + Co – TE	31.00	22.40	[95]
$O_2 + SO_3^{2-}$	30.8	58.1	[96]
(at pH 8.0; $[Co^{2+}] = 0.1$ mmol/L as catalyst)			

∗ MIPA = monoisopropanolamine;
TE = tetraethylenepentamine; other abbreviations are defined in Table 4.

The reaction rate constant k_{11} is calculated in $m^3\,kmol^{-1}\,s^{-1}$; from equation (145) by using $R = 0.008314$ kJ mol^{-1} K^{-1} for the gas constant and expressing the temperature T in Kelvin. In Table 5, Co – TE denotes a complex of cobalt (II) with tetraethylenepentamine, which forms a nitrosyl compound with nitric oxide. Numerical values of the reaction rate constants of nitric oxide with similar cobalt and iron complexes in aqueous solution have also been published [95], [97], and [98]. BRØNSTED has given a relationship between the reaction rate constant k_{11} of carbon dioxide with alkanolamines and the dissociation constand K_a of these alkanolamines, which suggests a homogeneous base catalysis, the following relation is recommended for primary and secondary alkanolamines [93]:

$$\ln k_{11} = \mathrm{p}K_a + 16.26 - 7188/T \tag{146}$$

This empirical formula applies from 293 to 303 K. For tertiary alkanolamines at 293 K,

$$\ln k_{11} = \mathrm{p}K_a - 14.24 \tag{147}$$

is recommended [93]. Some industrially important reactions are of a higher order, e.g., the reaction of carbon dioxide with the alkanolamines

DEA or DIPA, shown in Figures 5 and 6. For higher order reactions,

$$r = k_{mn}\,[\mathrm{A}]^m\,[\mathrm{B}]^n \tag{148}$$

the Hatta number according to HIGBIE is

$$Ha = k_1^{-1} \cdot \left[2 D_{\mathrm{AL}}\, k_{mn} \left(c_{\mathrm{A}}^{\mathrm{i}}\right)^{m-1} \left(c_{\mathrm{B}}^{\mathrm{b}}\right)^n / (m+1)\right]^{1/2} \tag{149}$$

These reactions probably occur according to the following mechanism [88], [100]. Carbon dioxide forms a zwitterion with an alkanolamine which, in a subsequent reaction, donates a proton to a base and is converted to the carbamate:

$$CO_2 + R_2NH \underset{k_1}{\overset{k_{11}}{\rightleftharpoons}} R_2NHCO_2 \tag{150}$$

$$R_2NHCO_2 + B \overset{k_2}{\rightleftharpoons} BR_2NHOO^- + BH^+ \tag{151}$$

Figure 5. Rate constant for the reaction of carbon dioxide with diethanolamine – effect of amine concentration
Temperature = 298 K.
+ Data from [91]; o Data from [101]; × Data and calculation [99]: $k_c = A/(1/1410 + 1/1200\,A)$

Figure 6. Rate constant for the reaction of carbon dioxide with diisopropanolamine – effect of amine concentration
Temperature = 298 K.
o Data from [101]; × Data from [93]

In the second reaction (Eq. 151) the proton can be accepted by various bases for example, OH^- ($\rightarrow H_2O$), water ($\rightarrow H_3O^+$), or an amine ($\rightarrow$ amine H^+). After the concentration of the zwitterion $[R_2NHCO_2]$ is eliminated mathematically, from the kinetics of Equations (150) and (151),

$$r = \frac{\mathrm{d}\,[\mathrm{CO_2}]}{\mathrm{d}t} = \frac{k_{11}\,[\mathrm{CO_2}]\,[\mathrm{R_2NH}]}{1 + k_{-1}/\sum k_{\mathrm{B}}\,[\mathrm{B}]} \tag{152}$$

If the increase in concentration of bases, [B], is proportional to the amine concentration

$$[B] = K_{\mathrm{B}}\,[\mathrm{R_2NH}] \tag{153}$$

and the denominator of Equation (152) is

$$1 \ll k_{-1}/\sum k_{\mathrm{B}}\,[\mathrm{B}] \tag{154}$$

the reaction tends toward third order and the reaction rate is proportional to the square of the amine concentration

$$r \approx \left(\sum k_{\mathrm{B}} k_{11} K_{\mathrm{B}}/k_{-1}\right)[\mathrm{CO_2}]\,[\mathrm{R_2NH}]^2 \tag{155}$$

Numerical values for the rate constants and energies of activation of reactions of carbon dioxide with aqueous and alcoholic solutions of DEA, MEA, and DIPA are given in [93], [101], and [102].

2.6. Modeling of Mass Transfer with Chemical Reaction

An analytical solution of the differential equations for mass transfer with a reaction of the absorbed component in the liquid phase is known only for a (pseudo) first-order reaction. This reaction must be either irreversible or coupled with a rapid secondary reaction of the products so that re-formation of the absorbed components need not be considered. Formulas derived for the following three models are known.

1) *Penetration Theory* (**Danckwerts**, **Higbie**):

$$k_1' = k_1 Ha \left(1 + 1/8Ha^2\right) \operatorname{erf}\left(2Ha/\pi^{1/2}\right) + 2Ha \exp\left(-4Ha^2/\pi\right) \quad (156)$$

2) *Two-Film Theory* (**Sherwood** and **Pigford**):

$$k_1' = k_1 Ha/\tanh Ha \quad (157)$$

3) *Surface-Renewal Theory* (**Danckwerts**):

$$k_1' = k_1 \left(1 + Ha^2\right)^{1/2} \quad (158)$$

Here, Ha is the Hatta number $(D_{\mathrm{AL}} k_{\mathrm{c}}/k_1^2)^{1/2}$, k_1' is the mass transfer coefficient with chemical reaction in the liquid phase in m/s; k_1 is the mass transfer coefficient in the liquid phase (with no reaction) in m/s; k_{c} is the reaction rate constant of the (pseudo) first-order reaction in s^{-1}, and D_{AL} is the diffusion coefficient of absorbed component A in liquid phase L in m^2/s.

A reaction of higher order

$$A + n\mathrm{B} \rightarrow \text{Product} \quad (159)$$

and its reaction rate r

$$r = k_{1n} [\mathrm{A}] [\mathrm{B}]^n \quad (160)$$

can be considered pseudo-first order with respect to A as long as the reaction partner B is not consumed to any great extent. Until then,

$$r = k_{\mathrm{c}} [\mathrm{A}], \text{ where } k_{\mathrm{c}} = k_{1n} [\mathrm{B}]^n \quad (161)$$

All three models lead to similar results [103]. No analytical solution of the differential equations is known for reversible reactions: other models or numerical methods are used to solve differential equations.

To represent the absorption kinetics of carbon dioxide and hydrogen sulfide in aqueous solutions of DIPA and MDEA the two-film theory with two layers is used [104]. The assumption is that the reaction is an irreversible first-order reaction and that the concentration profiles are linear [105]. If the boundary values from Danckwert's model are used for the concentration gradient of both layers, the differential equations can be replaced by nonlinear algebraic equations and solved numerically. This model was used by Shell Oil in the design of commercial installations for the selective absorption of hydrogen sulfide from gases containing carbon dioxide.

With the aid of a computation model based on the penetration theory, the differential equations for mass transfer, including complex reversible reactions in the liquid phase, can be solved numerically [106]. The concentration gradients are calculated by using a grid, the differential equations being replaced by a system of linear equations. Further computational models can be found in [107] and [108].

A professional simulation program dealing with kinetics and absorption is available under the name Aspen plus, which offers the method Ratefrac.

3. Design of Absorption Systems

3.1. Methods of Absorption

The use of *physical absorption* processes is preferred whenever

1) feed gases are present in large amounts at high pressure and the amount of the component to be absorbed is relatively large;
2) the purified gas (the fraction of gas that is not absorbed) must be of high purity;
3) one or more selectively absorbed components are to be obtained in enriched or pure form, possibly still at elevated pressure;
4) the absorbent is also the product of a subsequent synthesis, e.g., methanol (→ Gas Production).

On the other hand, absorption processes with simultaneous chemical reaction (*chemisorption*) are always preferred when

1) the components to be separated from feed gases are present in small concentrations and at low partial pressures;
2) the purity requirements of the purified gas are not too high;
3) the components to be separated from feed gases are strongly acidic and undergo a thermally reversible reaction with the chemical component of the absorbent;
4) low-cost waste heat is available for thermally regenerating the absorbent.

Absorption equipment for both types of absorption generally consists of a column with internals for heat and material exchange (plate or packing) in which the feed gas is brought into countercurrent contact with the regenerated absorbent.

The purified gas is taken off the head of this column. The absorbent loaded with the removed component, the absorbate, leaves the bottom of the column and is regenerated by desorption. The basic scheme thus consists of an absorption and a desorption stage with the absorbent cycling between them as it takes up and again gives off the absorbate (Fig. 7).

3.2. Methods of Desorption

Desorption (→ Gas Production) is the reverse process of absorption in which the absorbate is again removed from the solvent. Desorption is achieved with the following methods:

1) Flashing the solvent to lower the partial pressure of the dissolved components, to vacuum if necessary;
2) Reboiling the solvent, to generate stripping vapor by evaporation of part of the solvent;
3) Stripping with an (extraneous) inert gas;
4) A combination of methods 1 to 3.

Organic solvents can also be dried during desorption, when the water vapor absorbed with the feed gas is again given off. This leads to a dry clean gas with reduced vapor dew point.

Desorption occurs by the same basic mechanism as absorption. Each reduction in partial pressure of the absorbed component over the loaded solvent produces a desorption effect. Wide use is made of desorption by *pressure reduction* because the energy requirements are low and cover energy can even be recovered. In the second regeneration step after depressurization, stripping with inert gas is often more economic than thermal regeneration.

The desired purity of the gas determines the final cost of desorption. The necessary difference between the partial pressure of the absorbed

Figure 7. Schematic of absorption installation with desorption for regeneration
a) Absorber; b) Depressurization (flash) stage; c) Desorber (regenerator); d) Pump; e) Reducing valve; f) Cooler

key componentover the regenerated solution (1) and in the purified gas (2) serves as a criterion for determining the dimensions of the absorption and desorption equipment.

3.3. Absorption and Desorption Equipment

Because reactions and conversions between gaseous and liquid phases are substantially slower than those between equal states of aggregation, relatively large reaction volumes are required in gas absorption installations. Mechanical accessories which create the largest possible phase interface serve to improve mass exchange in sorption equipment. Relatively large gas and liquid velocities produce high turbulences as the hydraulic flooding point is approached.

Appropriate internals direct the liquid and gas streams and increase the contact area between the two phases, thereby substantially improving mass transfer. Various designs have proved suitable, especially absorption plates, randomly poured packings and structured packings (→ Distillation and Rectification, Chap. 8.3.).

The internals must be designed to withstand high hydraulic loads, produce minimum pressure loss and achieve good mass transfer with high separation efficiency. Various types of internals are described in [126–133].

3.4. Columns with Mass-Transfer Plates

Columns with mass-transfer plates have proved to be as suitable in absorption as in distillation (→ Distillation and Rectification, Chap. 8.1.3.). In comparison with most other internals, they are distinguished by high hydraulic flexibility, especially under extremely low load. Common characteristics of the most diverse designs of such plates are overflow weirs and downcomers for hydrostatic holdup of the liquid. Another type are dynamic plates without downcomers, holding up the liquid by the kinetic energy of the rising gases.

Valve plates (*ballast plates*) are widely used [130]. The *Varioflex Plate* (Stahl) has proved itself in practice. It is distinguished particularly by its lower hydraulic loading limit of 20 % and its very small pressure drop. High flexibility is achieved by the movable plate inside the fixed cap, whose lifting motion is always synchronized with the gas loading. In more recent designs the valve tray is perforated so that an even wider loading range can be achieved [131].

The *Cross-Stream Plate* (Montz), a valve plate without moving parts, is intended for especially high gas loading. The rectangular valves are arranged so that the gas streams intersect with neighboring streams and head-on collisions of opposing streams are thus prevented. In this manner, the otherwise inevitable upward entrainment of liquid is avoided [131].

Sieve plates are suitable for high gas loadings. They are needed to prevent liquid weeping through the plate (→ Distillation and Rectification, Chap. 8.2.). Good mass transfer occurs due to the bubble layer formation on the plate. The sieve plate can also be designed to have several downcomers. Except for special low-temperature separation plants, it has thus far not been widely used in absorption technology.

The *Kittel Polygonal Plate* (Stahl) is especially suited for high liquid loadings. The downcomers can be positioned inside or outside the plate. Some types have an internal tube in the center of the plate which is used to transport liquid or gas [132].

The *Performkontact Plate* (CLG) is also a cross-flow plate with downcomers for high liquid loading. Its active surface consists of expanded metal arranged so that the gas slots in the mesh are at an acute angle to the flow direction of liquid flows [133], [134].

3.5. Columns with Random Packing

Packings can take high liquid loads and have a low pressure drop. In addition to the well-known and well-tested Raschig rings, Pall rings, Berl saddles and Intalox packings [135–139] (→ Distillation and Rectification, Chap. 8.3.) new developments contribute to further reduction of the pressure drop occurring with increased mass transfer. Thus, for example, *Cascade mini rings* (Mass Transfer, Inc.) are used in a wide range of applications and excel by virtue of high performance [140].

Intalox metal saddles also have special advantages [141–144]. *Super-intalox* (R) packings of plastic and ceramic materials (Norton) are used often in practice and are distinguished by high capacities and good separation performance [145]. Compared to steel packings, thermoplastic packings are not only lighter but frequently also more cost-effective. In contrast to ceramic packings, they do not exhibit abrasion. Stabilizing additives ensure that their temperature resistance is relatively high. Wetting of plastic packings can be improved substantially by hydrophilic surface treatment which eliminates this disadvantage compared with metal packings [146].

The new *VSP packing* (Vereinigte Füllkörper Fabriken) also shows high performance. This packing has better properties than the classical Pall rings and may also be somewhat more cost-effective [148], [149].

3.6. Columns with Structured Packing

Structured packings for columns have come into increasing use. Their efficiency often considerably exceeds that of conventional random packings.

Thus, packings of metal, synthetic woven fabrics and ceramics such as *Mellapack* (metal) and *Kerpak* (ceramics) have been used (Sulzer) (→ Distillation and Rectification). Existing columns can be retrofitted with such packings to increase their capacity [150], [151].

Special requirements tailored to specific separation problems can be met with *Pyrapack* packings G and F [152], [153]. The elements are fabricated from expanded metal (CLG). Type F packing has a greater specific surface and thus achieves a high specific separation performance. Variant G is coarser and is mainly used for high gas and liquid loading.

Increased packing surfaces in connection with additional turbulences in the liquid film are achieved with *Rombapak* (Kühni) by means of finely grooved surfaces. The distribution of liquid is significantly improved, and a separation performance of 3.5 – 4 separation stages per meter of packing height is achieved [154].

3.7. Columns with Special Internals

Atomizing absorbents in spraying devices, e.g., through nozzles, produces a suspension of finely divided drops in a stream of gas. Such absorption methods are suitable for highly soluble components if resistance to mass transfer occurs primarily in the gas phase. The ratio of absorbent to gas can then often be very small and contact times can be short.

Scrubbers with several series of nozzles and short contact times are successfully employed for these tasks. The size of the droplets and the residence time for a given gas throughput can be adjusted appropriately by a suitable choice of nozzles shapes [118].

Cyclone scrubbers can be used whenever a single absorption stage is sufficient. The liquid drops are injected, entrained by the high-velocity gas, loaded with absorbate and separated at the wall.

This group also includes *Venturi scrubbers* (→ Dust Separation, Chap. 4.2.) in which the liquid is separated from the gas at the outlet. In addition to their original application for separating such particles as dust, mist, or aerosols, they are increasingly used in absorption technology (e.g., of sulfur dioxide in flue gas scrubbers) or in chemisorption (e.g., of hydrogen sulfide in oxidative scrubbers).

However, Venturi scrubbers normally reach only moderate absorption efficiencies of about 95 % and their pressure drop of 2.0 – 5.0 kPa is relatively high.

Absorption equipment with rotating internals to disperse the solvent (e.g., "*High Gee*") has so far not been widely accepted. Practical applications were limited to special cases [155], [156]. Spraying devices generally require too much energy to be cost-effective.

Film scrubbers are used for absorption particularly when large absorption enthalpies have to be removed at the same time, e.g., for the absorption of hydrogen chloride in water. Tube walls on which the absorbent trickles down can easily be cooled with water on the other side. In the case of an "adiabatic absorber" the reaction enthalpy, e.g., from hydrogen chloride absorption, is also removed by water evaporating from the upper end of the tube [114].

The absorption efficiency can be improved by installing "mechanical stirrers" which increase

the path of the gas bubbles and mix the liquid more thoroughly. Stirrer vessels are normally employed for systems in which the resistance to mass transfer occurs in the liquid phase. This may be the case for aeration basins of oxidative scrubbers or open wastewater treatment basins if oxygen has to be injected into the liquid.

4. Design of Absorption Equipment

Graphical and analytical methods are used to design absorption equipment [157]. Usually, a material and heat balance is drawn up first. The absorbed component in each case should preferably be referred to the pure absorbent at a predetermined temperature (e.g., 20 °C). In this way, stationary mass flows are defined.

4.1. Physical Absorption in Plate Columns

For component i to be absorbed, the material balance for the absorber with cross-section a – a (see Fig. 8) is, for the lower section:

$$G_1 \cdot y_1 + L \cdot c = G \cdot y + L \cdot c_1 \tag{162}$$

for the upper section:

$$G \cdot y + L \cdot c_2 = G_2 \cdot y_2 + L \cdot c \tag{163}$$

with:

$$G\,(1-y) = G_1\,(1-y_1) = G_2\,(1-y_2) \tag{164}$$

where G_1 is the flow rate of gas entering the absorber; G_2 the flow rate of gas leaving the absorber; y_1 the gas phase mole fraction of absorbate entering the absorber; y_2 the gas phase mole fraction of absorbate leaving the absorber at the heat; L the flow rate of the solvent; c_1 the concentration of absorbate leaving the absorber at the bottom; and c_2 the residual load of absorbate in the regenerated solvent entering the absorber.

Solving for c, the concentration after loading, gives:

$$c = c_2 + \frac{G_1}{L} \cdot \frac{1-y_1}{1-y_2} \cdot \frac{y-y_2}{1-y} \tag{165}$$

with

Figure 8. Absorption by a solvent in an absorption column

$$\frac{G_1}{L} \cdot \frac{1-y_1}{1-y_2} = \text{constant},$$

the balance or operating line of the absorber is

$$c = c_2 + \text{const.}\,\frac{y-y_2}{1-y} \tag{166}$$

If the operating line and the equilibrium line are plotted on a concentration-loading diagram the curves shown in Figure 9 are obtained. For constant streams of liquid and gas, the balance line is a straight line. The equilibrium line is obtained by the method described in Chapter 2.

Figure 9. Loading diagram for determining theoretical number of separation stages for isothermal absorption

The equilibrium line in Figure 9 is plotted for a constant temperature, which is permissible only for isothermal absorption. With the aid of a set of steps drawn between the equilibrium line and the operating line from y_1 to y_2, the number of theoretical separation stages can be determined. The number of theoretical separation stages depends on the absorbent flow rate L. The less absorbent enters the absorber, the smaller will be the slope of the operating line and the more stages are needed for a given separation problem. If the operating line and the equilibrium line intersect, the number of separation stages is infinite. To increase the slope of the operating line it is necessary to increase the absorbent flow rate.

A theoretical separation stage is characterized by:

1) perfect phase equilibrium between gas and absorbent,
2) complete mixing of the liquid on the plate of the separation stage, the concentration of liquid above the plate being constant, and
3) flow of gas to the next plate without entrained absorbent droplets.

Practically, phase equilibrium is never reached completely with the plates in commercial installations. Also, droplets are frequently entrained with the gas and a concentration gradient occurs above the plate. The combined effect of these "imperfections" is reflected by the degree of plate efficiency.

Although different values are obtained, depending on the principle of plate construction and the pairing of materials, the degree of efficiency in absorption technology is generally about 18 – 25 % for poorly soluble components and 30 – 40 % for readily soluble components. This is clearly below the degrees of efficiency attainable in distillation technology (→ Distillation and Rectification).

Once the number of theoretical separation stages is known, the practical number of plates has to be defined for each theoretical stage, using this degree of efficiency. The practical number of absorption plates required is extremely important for the economy of an absorption process. Therefore, an optimum balance must be achieved between excess of absorbent and minimum number of plates in the column.

The minimum amount of absorbent required is obtained from the slope of the operating line for an infinite number of theoretical separation stages. It is given by the ratio of absorbent to the total gas rate:

$$\frac{L_{\min}}{G}=\frac{y_2-y_1}{c_2-c_1}=\frac{\Delta y}{\Delta c}$$

$$L_{\min}=\frac{G}{\alpha_i \cdot P_{\mathrm{g}}} \tag{168}$$

where α_i is the solubility coefficient of component i and

$$c_{\mathrm{i}}=\alpha_i \cdot p_i=\alpha_i \cdot y_i \cdot P_{\mathrm{g}} \tag{169}$$

To determine the true amount of absorbent, $L_{\min}$ is multiplied by an absorption factor A for the excess of solvent

$$L=A \cdot L_{\min} \tag{170}$$

The absorption factor A must always be chosen such that the operating line is steeper than the equilibrium line, i.e., it must be greater than 1. If the equilibrium line is a straight line, the absorption factor is the ratio of the slope of the operating line to that of the equilibrium line. For a mixture of gases, the theoretical stage number can be determined graphically for each individual component to be absorbed. When this is done, different numbers of required theoretical stages are usually obtained. In such a case, A is calculated by using the critical component for the absorption process (key component).

Next, the rest content of each individual component at the head of the absorber is determined with this selected absorption factor A and the appropriate equilibrium line, starting with the loading at the bottom. If the purity requirements for a component are not met, the operating line and/or the absorption factor A have to be changed.

The design of columns for the absorption of multiple components can be calculated by a number of methods, largely supported by computers. Plate-to-plate calculations have been successfully carried out with variable gas and liquid streams and with variable absorption and desorption factors [158–161].

Concepts which have been introduced to good advantage in absorption technology are the *absorption rate* E_{A} and the *absorption coefficient* φ_{A} (see Figs. 10 and 11, next two pages).

Figure 10. Degree of absorption or desorption as functions of the absorption and desorption factors A and D, respectively, and of the theoretical plate number n_{th} according to Equation (177)

The (percent) absorption coefficient φ_{A} of a component i from a gas which can be attained in case of incomplete regeneration is defined as

$$\varphi_{\mathrm{A}}=\frac{y_2-y_2^*}{y_1-y_2^*}=\frac{y_{\mathrm{h}}-y_{\mathrm{h}}^*}{y_{\mathrm{s}}-y_{\mathrm{h}}^*} \tag{171}$$

Substituting the relation

$$y_{\mathrm{h}}^*=\frac{c_{\mathrm{h}}^*}{\alpha_i^*\cdot P_{\mathrm{g}}} \tag{172}$$

for the equilibrium content of the gas phase $y*_{\mathrm{h}}=y*_2$ and designating the slope of the equilibrium line as

$$\frac{1}{\alpha_i^*\cdot P_{\mathrm{g}}}=m \tag{173}$$

the absorption rate E_{A} is obtained as

$$E_{\mathrm{A}}=\frac{y_1-y_2}{y_1-m\cdot C_2^*}=\frac{y_{\mathrm{s}}-y_{\mathrm{h}}}{y_{\mathrm{s}}-m\cdot c_{\mathrm{h}}^*} \tag{174}$$

If the amount of component i in the absorber head approaches the equilibrium value, than

$$y_{2i}=y_{2i}^* \text{ or } y_{\mathrm{h}i}=y_{\mathrm{h}i}^* \tag{175}$$

the absorption rate $E_{\mathrm{A}}=1$, i.e., the maximum possible amount of component i has been absorbed from the gas. The absorption factor A, defined as the ratio of the slopes between the operating line and the equilibrium curve, can also be written as

$$A=\frac{y_1-y_2}{y_1^*-y_2^*}=\frac{y_{\mathrm{s}}-y_{\mathrm{h}}}{y_{\mathrm{s}}^*-y_{\mathrm{h}}^*} \tag{176}$$

Combining the relations for the absorption rate (Eq. 174) and the absorption factor (176) for arbitrary numbers of theoretical stages n_{th} yields [158]

$$E_{\mathrm{A}}=\frac{A^{n_{\mathrm{th}}+1}-A}{A^{n_{\mathrm{th}}+1}-1} \tag{177}$$

Equation (177) is plotted in Figure 10 for various theoretical stage numbers between 1 and 20. The limiting tangent of this family of curves is the line for infinitely large theoretical stage numbers.

With the aid of Figure 10, the required theoretical plate numbers can be determined both for absorption, by using the absorption factor A, and for desorption, by using the desorption factor D, if

1) gas and liquid loading in the column are constant,

Figure 11. Absorption and desorption coefficient φ_A and φ_D as a function of the theoretical stage number n_{th} depending on the absorption and desorption factor *A* and *D* (Eq. 179, 180)

2) absorption or desorption is isothermal,
3) the absorbate is present at low concentrations, and
4) the solubility coefficient α_i is constant.

Equation (178) shows the dependence of the theoretical stage number n_{th} on the absorption factor *A*:

$$n_{th}=\frac{\ln\left[\frac{y_1-y_2^*}{y_2-y_2^*}\cdot\left(\frac{A-1}{A}\right)+\frac{1}{A}\right]}{\ln A} \tag{178}$$

Here, $y*_2$ is the equilibrium concentration of the gas phase pertaining to the liquid with residual loading c_2 in the absorber head. Analogous to the absorption factor *A*, the desorption or stripping factor *D* can be used to determine the theoretical stage number n_{th} of the desorber.

By relating the difference between actual and equilibrium concentration in the absorber head for the gas phase (y_2-y_2*) and for the liquid phase (c_2-c*_2) to the change in concentration at the bottom of the absorber for the gas phase (y_1-y*_1) and for the liquid phase (c_1-c*_1), the following relation is obtained for the absorption coefficient:

$$\varphi_A=\frac{y_2-y_2^*}{y_1-y_2^*}=\frac{y_2-m\cdot c_2^*}{y_1-m\cdot c_2^*}$$

or

$$\varphi_A=\frac{y_h-y_h^*}{y_s-y_h^*}=\frac{y_h-m\cdot c_h^*}{y_s-m\cdot c_h^*} \tag{179}$$

Analogously, for desorption

$$\varphi_D=\frac{c_1-c_1^*}{c_2-c_1^*}=\frac{c_1-\frac{1}{m}\cdot y_1^*}{c_2-\frac{1}{m}\cdot y_1^*}$$

or

$$\varphi_D=\frac{c_s-c_s^*}{c_h-c_s^*}=\frac{c_s-\frac{1}{m}\cdot y_s^*}{c_h-\frac{1}{m}\cdot y_s^*} \tag{180}$$

This correlation is illustrated graphically in Figure 11 using φ_A and φ_D respectively as ordinate and the theoretical stage number n_{th} as abscissa and the absorption or desorption factor *A, D* as parameter. The assumptions already mentioned for Figure 10 apply also to this diagram.

4.2. Chemisorption in Packed Columns

Chemisorption normally uses columns with packings or similar internals. Mass transfer occurs along the trickling film of the packing and calculating the required column height becomes difficult. Hence, packed columns are often calculated according ot the concept of theoretical separation steps. However, experimental data are required as a rule to get the true number of theoretical separation stages per meter of packing height for given packings and material systems.

Colburn [162] introduced a method in which the region of separation is subdivided into a number of consecutive mass exchange units, the so-called number of transfer units (NTU). The sum of the transfer units is called N_{tot}. The transfer unit *N* must be related either to the gas phase or to the liquid phase, N_G or N_F, respectively.

The transfer unit N is a pure thermodynamic quantity representing the driving force of the equilibrium process. It is a measure of the deviation from thermodynamic equilibrium and depends on mass transfer.

A simple relation for determining the sum of the transfer units in the gaseous phase $N_{\mathrm{G,tot}}$ is obtained by analogy to the corresponding relation (178) for plate columns. For absorption

$$N_{\mathrm{G,tot}} = \frac{A \cdot \ln\left[\frac{y_1 - y_2^*}{y_2 - y_2^*}\left(\frac{A-1}{A}\right) + \frac{1}{A}\right]}{(A-1)}$$

or

$$N_{\mathrm{G,tot}} = \frac{A \cdot \ln\left[\frac{y_{\mathrm{s}} - y_{\mathrm{h}}^*}{y_{\mathrm{h}} - y_{\mathrm{h}}^*}\left(\frac{A-1}{A}\right) + \frac{1}{A}\right]}{(A-1)} \tag{181}$$

A corresponding relation can be derived for desorption as a function of loading c.

Figure 12 shows the absorption coefficient φ_{A} or the desorption coefficient φ_{D}, respectively, plotted as a function of $N_{\mathrm{G,tot}}$. The absorption and desorption rates are defined analogous to those for plate columns (Fig. 10). Other calculation methods for determining transfer units will be found in the literature [163].

In addition to the number of required (theoretical) transfer units N_{tot}, another practical equivalence value corresponding to the transfer unit $N_{\mathrm{G,tot}} = 1$ is needed for the calculation of packed columns. This is the *height of transfer unit* (HTU) which can be referred to either the gas or the liquid phase. The practical total packing height h of a packed column is then

$$h = h_{\mathrm{G,tot}} \cdot N_{\mathrm{G,tot}} = h_{\mathrm{F,tot}} \cdot N_{\mathrm{F,tot}} \tag{182}$$

The transfer units $h_{\mathrm{G,tot}}$ or $h_{\mathrm{F,tot}}$ are best determined on actual working columns. If such practical data are not available, packed columns can also be calculated by a number of methods found in the literature [157].

Nevertheless, despite the increasing accuracy of these often highly complex calculations, it has always been necessary to subject them to a practical test.

4.3. Nonisothermal Absorption

Only if the component to be absorbed from the gas mixture (key component) is present in low concentrations will the thermal effect be so small that the absorption can be regarded as being virtually isothermal. If the key component is present in larger amounts, the solvent will be heated by taking up enthalpy of absorption because physical processes of absorption are as a rule exothermic. Part of the enthalpy of absorption is then transferred to the gas.

In chemisorption, this effect is produced by the enthalpy of the reaction which, as a rule, entails greater heat effect. This temperature increase has such a strong effect on the equilibria along the height of the column that it must be taken into account in the calculation.

Figure 12. Absorption and desorption coefficient φ_{A} and φ_{D} as a function of the number of transfer units $N_{\mathrm{G,tot}}$ with absorption and desorption factor A and D as parameters (Eq. 181)

The enthalpy of absorption is approximately equal to the enthalpy of condensation only for components of the gas present in sub-critical concentrations. For super-critical components it must be calculated from known equilibrium values (see Section 1.6).

In nonideal mixtures, the enthalpy of mixing (excess enthalpy) appears in addition to the enthalpy of condensation. The total enthalpy of absorption consists of the enthalpy of condensation and the differential enthalpy of solution.

The enthalpy of absorption depends on the concentration but often only slightly on temperature. To determine the equilibrium line for nonisothermal absorption, a temperature profile along the column must be given or calculated. In the simplest case, a linear relation with the loading of the solvent is assumed:

$$\frac{\Delta c}{\Delta t} = \text{const.} \tag{183}$$

To determine the equilibrium line for constructing the McCabe – Thiele diagram (→ Distillation and Rectification,, Chap. 3.1.1.), the equilibria at different temperatures must be known.

For given loadings and known average enthalpies of solution and specific heats, the temperatures of the solvent at the various equilibria can then be determined from the material and heat balances for adiabatic absorption. A characteristic of the equilibrium line is then obtained as shown in Figure 13.

Figure 13. Equilibrium curve for nonisothermal absorption superimposed on equilibrium curves at constant temperatures T_1 to T_5

5. Design of Desorption Equipment

[164–169]

5.1. Physical Desorption in Flash Columns

When the total pressure of physical solvents containing dissolved gases is reduced, the gases desorb until a new equilibrium is established. This is by far the most economical method for regenerating loaded solvents.

This pressure reduction occurs predominantly isenthalpic, i.e., without performing work, by way of butterfly valves. If the quantities of solvent are large and the pressure differential great, using flash turbines, that perform work (Francis or Pelton turbines, or even a reverse running pump) is recommendable.

To calculate the amount of gas that has to be flashed per stage in order to reach a specified pressure it may generally be assumed that the rate of desorbed gas is in equilibrium with the regenerated solvent. A flash stage thus corresponds to a theoretical separation stage.

The new equilibrium at the reduced pressure is again calculated via the material and enthalpy balance for the dissolved component *i*, with the nomenclature used in Figure 14.

$$L \cdot c_4 = L \cdot c_3 + y_4 \cdot G_4$$
$$L \cdot (c_4 - c_3) = y_4 \cdot G_4 \tag{184}$$

where c_4 is the concentration of component *i* in the absorbent entering the flash column, c_3 is the concentration of *i* in the absorbent leaving the column, G_4 is the flow rate of flash gas, and y_4 is the mole fraction of component *i* in the flash gas with

$$\gamma = \frac{G}{L} \text{ (relative gas volume)} \tag{185}$$

then

$$y_4 = \frac{c_4 - c_3}{\gamma} = \frac{c_4}{\gamma} - \frac{c_3}{\gamma} \tag{186}$$

The absorption equilibrium after flashing is:

$$c_3 = \alpha_i^* \cdot p_3^* \tag{187}$$

Figure 14. Isenthalpic depressurization of a loaded solvent in a flash column

By combining equations (186) and (187), the concentration of component i in the flashed gas is:

$$y_4 = \frac{c_3}{\gamma} - \frac{\alpha_i^*(t_4) \cdot P_4^*}{\gamma} \tag{188}$$

Strictly speaking, this relationship is valid only for ideal gas behavior, as is usually the case at reduced flash pressure. At higher total pressure the real gas behavior must be taken into account by introducing fugacity coefficients (see Chap. 1).

Equation (177) serves for iterative flash calculations. The flash temperature t_3 and the flash concentration y_4 must initially be estimated for each component in a first pass. Here, the gas volume referred to L must be chosen such that the boundary condition

$$\Sigma y_i = 1 \tag{189}$$

is met for all desorbed components. For the enthalpy balance about the flash stage

$$Q_{\mathrm{L},4} = Q_{\mathrm{G},4} + Q_{\mathrm{L},3} + Q_{\mathrm{D}} \tag{190}$$

where Q_{D} is the enthalpy of desorption, or $L \cdot c_{\mathrm{p,\,m}} \cdot t_4 = G_4 \cdot c_{\mathrm{p,\,m}} \cdot t_4 + L \cdot c_{\mathrm{p,\,m}} \cdot t_3 + Q_{\mathrm{D}}$ The flash temperature t_4 can be eliminated by combination with Equation (185) to obtain

$$t_4 = t_3 = \frac{C_{\mathrm{P,m}} \cdot t_4 - \frac{Q_{\mathrm{D}}}{L}}{v \cdot C_{\mathrm{P,m,G}} + C_{\mathrm{P,m,L}}} \tag{191}$$

Equation (180) provides a relation between the flash temperature $t_4 = t_3$ and the flow rate of flash gas G_4 at a given flash pressure. For physical systems, the enthalpy of desorption Q_{D} is generally not very temperature-dependent. Equations (188) and (191) are conveniently solved by iteration on computers. In doing so, the time required for the calculation can be reduced by using suitable initial values from experience with known material systems.

If the solvent is desorbed by flashing to atmospheric pressure, the partial pressure of the key component that can be attained is about 0.11 to 0.12 MPa. With direct recycling to the absorber, this permits only moderate gas purities so that this method is adequate only for bulk removal of gaseous components or as a prestage for fine regeneration. Another flash stage operating under vacuum may be provided in order to further reduce this partial pressure. Further reduction of the partial pressure can be achieved also by bringing the absorbent into contact with an inert gas. This is more economical even in most cases. Also a combination of vacuum regeneration and stripping with inert gas is frequently a good method.

5.2. Physical Desorption in Stripper Columns

Desorption of a loaded absorbent by stripping with an inert gas has the advantage that the absorbent usually does not have to be heated or evacuated. This method of regeneration can be used also at elevated temperatures, thereby reducing the amount of stripping gas required.

To design such a stripper column, the operating line is again determined from a balance in addition to the equilibrium line. The material balance for the stripper column is calculated in the cross-section a – a according to Figure 15

Figure 15. Desorption of a loaded solvent by stripping in a stripper column

for a given component *i*, by following the same principle as for absorption (Chap. 4).

For the *lower part*

$$L \cdot c + G_5 \cdot y_5 = L \cdot c_5 + G \cdot y \tag{192}$$

and for the *upper part*

$$L \cdot c_6 + G \cdot y = L \cdot c + G_6 \cdot y_6 \tag{193}$$

where G_5 is the flow rate of strip gas entering the stripper column, G_6 is the flow rate of gas leaving the stripper column, y_5 is the mole fraction of desorbed component *i* in the stripping gas, y_6 is the mole fraction of *i* in the gas leaving the stripper column, c_5 is the concentration of *i* in the absorbent leaving the stripper column, and c_6 is the concentration of *i* in the absorbent entering the column. The stripping gas balance in the lower part is

$$G\,(1-y) = G_5\,(1-y_5) \tag{194}$$

For each loading *c*, the operating line of the desorber is obtained as a function of the mole fraction *y* of the key component in the stripping gas

$$c = c_5 - \frac{y_5 \cdot G_5}{L} + \frac{y \cdot G_5}{L} \cdot \left[\frac{1-y_5}{1-y}\right] \tag{195}$$

If a pure inert stripping gas is used that does not contain fractions of the component to be desorbed $y_5 = 0$ and equation (195) simplifies to

$$c = c_5 + \frac{G_5}{L}\left[\frac{y}{1-y}\right] \tag{196}$$

Plotting the operating line determined according to Equation (184) on a concentration-loading diagram leads to the curve shown in Figure 16.

Figure 16. Loading diagram for determining the theoretical number of separation stages for isothermal desorption by stripping with inert gas

For constant liquid and gas streams, the balance or operating line for desorption, as for absorption, is a straight line. However, the operating line for desorption is below the equilibrium line. By using the same method employed in absorption, the number of theoretical separation stages required for nonisothermal desorption in a stripper column is obtained by drawing a series of steps between y_{h} and y_{s}. The theoretical number of separation stages for isothermal desorption can also be determined according to [158].

From the ratio of the slopes between the operating and the equilibrium line, the stripping factor *D* can be determined as shown in Section 4.1. Its relation to the absorption factor is

$$A = \frac{1}{D} \tag{197}$$

The isothermal desorption conditions represented in Figure 16 apply, strictly speaking, only to the low-loading common when stripping with inert gas. At high loading and without the use of an inert stripping fluid, desorption proceeds like distillation if the stripping vapor is generated by boiling and evaporation of the solvent.

5.3. Physical Desorption in Reboiler Columns

Here, nonisothermal desorption occurs by boiling the solvent at the bottom of the column. Temperature increases from the solvent inlet to the bottom of the column where it reaches the boiling point of the solvent. The component to be driven off, as a rule, boils at a lower temperature than the solvent. The rising vapor stream, consisting mostly of solvent, acts as a stripping fluid, supported, if necessary, by simultaneously desorbed inert gases.

Thermodynamically, this type of desorption is a distillation or rectification process (→ Distillation and Rectification). It is the most energy-consuming method for the regeneration of a loaded solvent.

To desorb dissolved hydrocarbons, for example, superheated (live) steam is often blown directly into the bottom of the column, producing an additional stripping effect that lowers the partial pressure similar to vacuum regeneration.

If the solvent has a high boiling point (a so-called high-boiler), boiling under vacuum is often required to attain high degrees of regeneration. If compared to stripping with inert gas, this method has the advantage that the component to be desorbed, usually hydrogen sulfide, is not unnecessarily diluted and is easier to recover in subsequent process steps (e.g., Claus units → Sulfur).

The design of reboiler columns follows the same principles as in distillation (→ Distillation and Rectification). Here, too, the use of equilibrium constants with K_i for the key component to be driven off and K_L for the solvent is advantageous.

For a binary mixture, the following equations apply to the key component *i* to be desorbed and the solvent L (see also Chapter 1):

$$K_i = \frac{y_i}{x_i} = \frac{y_i}{c_i}; K_L = \frac{y_L}{x_L} = \frac{y_L}{c_L}$$

$$\frac{K_i}{K_L} = \frac{y_i}{c_i} \cdot \frac{c_L}{y_L} = \frac{y_i\,(1-c_i)}{c_i\,(1-y_i)} \tag{198}$$

$$K_i\,K_L = \frac{P_i^s}{P_L^s} = \beta \tag{199}$$

$$y_i = \frac{\beta \cdot c_i}{1 + (\beta - 1) \cdot c_i} \tag{200}$$

In an equilibrium diagram, Equation (189) is a hyperbola (Fig. 17).

Figure 17. Loading diagram for determining the theoretical number of separation stages in nonisothermal desorption by reboiling

As in distillation, the reboiler column may consist of a distilling and a concentration section. The solvent loaded with load C_M is fed to the head of the column. In this case, the reboiler column consists only of a distillation section, the operating line being the distillation line R – G.

Only when the vapor pressures p_i^s of the components to be distilled and of the solvent p_L^s are very close, i.e., when β is relatively small, will a concentrating section G – P be needed. This section will then be placed above the solvent inlet. With the solvents used today, this is generally not necessary.

The theoretical number of separation stages in desorption is determined graphically by constructing a sequence of steps between head and bottom. The vapor rate to be produced by the reboiler in the column bottom is defined by the slope of the operating line. The minimum vapor rate for concentrations between $c_5 = c_s$ and c_M is given by the slope of the distillation line R – G.

The gaseous mixture leaving the uppermost plate of the column still contains a considerable amount of solvent vapor which is condensed in an overhead condenser. The condensate is generally used as reflux.

In addition to the production of stripping steam, the heat requirements of the reboiler column consist of the fraction needed to raise the temperature of the solvent if the latter is not supplied to the column at boiling temperature. If any low-boiling component, which desorb eas-

ily, are present in the solvent in addition to the key component, the heat requirements are even higher. In this case, their enthalpy of desorption must be taken into account.

Any higher boiling components in the solvent (e.g., hydrocarbons) are (1) either left in the solvent, because they desorb with difficulty, or (2) considerably increase the steam required for regeneration if they have to be distilled. In addition to the material balances, enthalpy balances are also calculated for the reboiler column in the usual way to finally determine the performance of the reboiler.

The spent solvent leaving the absorber is often cooled further in the subsequent flash regeneration stage. To minimize the energy required for the production of stripping steam, the solvent is heated in heat exchangers in counterflow to the hot solvent leaving the reboiler column. The design of these heat exchangers has to allow particularly for the inevitable degassing of easily desorbable gases. Otherwise, a so-called "back pressure" has to be applied to the solvent by means of an additional pump to avoid degassing of dissolved components.

5.4. Chemical Desorption in Reboiler Columns

Because of the parabolic form of the equilibrium curves in chemisorption, only a relatively small amount of gas can be desorbed from chemical absorbents by flashing. Regeneration occurs by increasing the temperature and reducing the partial pressure in a regenerator. Stripping vapor is normally generated by reboiling the solvent with steam.

Nevertheless, a physical flash stage frequently precedes this thermal regenerator, particularly if the absorption pressure is extremely high and a large fraction of valuable gases such as carbon monoxide, hydrogen and hydrocarbons, is coabsorbed in the water content of the solvent.

Chemically loaded absorbents are thermally regenerated in counterflow columns in the same way that is used for stripping regeneration of physical solvents (see Section 5.3).

Assuming that desorption in the regenerating column is isothermal, and neglecting the fact that the reduction in pressure leads to an increase in temperature, the conditions during chemical desorption are reflected by the loading diagram (Fig. 18). The theoretical number of separation stages is established as previously described by a sequence of steps.

The partial pressure of the component to be expelled is reduced by reboiling the solvent or by directly injecting live steam into the bottom of the regenerating column.

While the stripping vapor rises to the column head, if condenses partly, providing the desorption enthalpy for the components to be expelled. If the temperature of the spent chemical solvent is lower than the boiling temperature in the regenerator bottom, the heat required for heating it to the boiling point in order to produce stripping vapor must be supplied as well.

The steam demand of the reboiler is derived from an accurate regenerator heat balance.

Sufficient stripping vapor must remain at the regenerator head to sufficiently reduce the partial pressure of the component to be expelled relative to the total pressure. The resulting slope of the operating line is generally such that thermal chemical desorption requires a low number of theoretical plates, as shown in Figure 18.

Figure 18. Loading diagram for the isothermal desorption of a chemically loaded solvent by reboiling

Due to the inflection of the equilibrium curve, the difference in partial pressure in the regenerator bottom is considerably less than in the head.

As the stripping vapor rate G_h at the column head is required to make up for the difference between the total pressure p_g and the partial pressure of the key component p_1 as illustrated by point 1 in Fig. 18, the required stripping vapor rate G_h at the column head can be described by

$$G_h = \frac{L \cdot (c_h - c_s) \cdot (P_g - p_1)}{p_1} \tag{201}$$

The stripping vapor rate for the column bottom can then be derived from the regenerator heat balance according to Equation (190). If the residual partial pressure of the expelled component above the regenerated solvent is limited by the vapor requirement of the regenerator, the gas purity increases with higher pressure in the absorber. Chemical regeneration systems provide for heat exchange between the spent and the regenerated solvent in order to reduce the demand for stripping vapor.

Also in chemical desorption systems the stripping effect can be supported by an inert gas. If a dry inert gas is used, it takes up steam until it is saturated. The cooling effect in the regenerator due to this resaturation must be considered in the heat balance.

Whenever live steam is used for stripping, the solvent temperature cannot drop below the condensation temperature because the solvent is consistently reheated by the condensing steam. Stripping with live steam has the advantage that the pressure can be much lower than that of reboiler heating vapor because of the required temperature differential. However, because of an equalized water balance the live steam rate to be used for stripping is limited to that rate that leaves the regenerator and/or absorber together with the gases. Experience showed that the steam demand to regenerate chemically loaded solvents can also be reduced by a split-flow arrangement [114], [115].

1. Introduction

1.1. Definition and History

Physical adsorption commonly is understood as reversible binding of molecules and atoms from the gaseous or liquid phase on surfaces, mostly of highly porous adsorbent media. The reverse process is called desorption. In adsorption, the *adsorptive* accumulates on the *adsorbent* which is then loaded with *adsorbate.* During desorption, the adsorbate present in the condensed phase passes from the surface of the adsorbent into the fluid phase. Ad- and desorption are similar to condensation and sublimation, but fluid and solid are heterogeneous and the solid remains inert. Linguistically, “sorption” originates from the latin “sorbere” (to devour) and indicates an event of a certain vehemence. The suitable physical description is phase thermodynamics with an additional degree of freedom attributed to the surface. The basic statistical approach for adsorption phenomena is different to that for condensation and pore condensation: while surface adsorption is governed by individual statistics with occupation indices for characteristic adsorption sites of distinct binding energies, condensation is related to collective statistics with sharp phase transitions due to the loss of the surface degree of freedom. Adsorption events are accompanied by intensive heat production, volumetric contraction, and space confinement leading to saturation limits. The most prominent effect on adsorption, the volumetric contraction, has been known for more than two thousand years. Examples are water vapor adsorption by freshly sheared lamb's wool and the purification of contaminated water with charcoal. In both cases, finely structured surfaces are involved. Since the 1400s recovery of adsorbed water from air was used. Around 1780 the famous Genovian universalist HORACE BÉNÉDICT DE SAUSSURE measured the adsorption capacity of charcoal for a series of gases and showed that they could achieve loadings of about 25 % of modern activated carbons.

1.2. The Development of Adsorption Technology

The technical applications of adsorption cover a wide range, such as separation, synthesis, storage, purification of gases and liquids, and air conditioning, and reveal a multifacetted discipline within thermal and chemical engineering science. It is increasingly becoming established in chemical processes as an alternative to the conventional separation techniques of rectification, absorption, condensation, drying, extraction, membrane processes, and catalysis, and it profits from various and optimally tailored adsorbents.

The overlap with the thermal separation techniques mentioned above and with surface science and nanotechnology is considerable. To avoid confusion, the term “technical adsorption” can be restricted to processes involving highly porous media. The development and characterization of such media is one of the most challenging tasks of adsorption technology for the time being and in the future. The advent of molecular sieves in 1965 opened new dimensions for highly effective separations by providing highly versatile and advantageous technical adsorbents.

Our knowledge on adsorption is owed to exceptional scientists: SIR WILLIAM THOMSON, later LORD KELVIN, found the relation between adsorption energy and pore dimensions in 1850; JOSIAH WILLIARD GIBBS introduced the thermodynamic description of adsorption phenomena in 1876, WILHELM OSTWALD developed an isotherm equation at heterogeneous surfaces that is still valid today in 1885. MICHAEL POLANYI elucidated the relation between adsorption potential and adsorptive compression [1], and IRVING LANGMUIR derived the exact equilibrium equation under homogeneous conditions from ad- and desorption rates [2, 3].

With the beginning of the technical use of adsorption for the first industrial separation units in 1920, multilayer adsorption was described by BRUNAUER, EMMET, and TELLER in the form of the BET equation [4], which is still in use for adsorbent characterization. DUBININ proposed a correlation for predicting isotherms from liquid properties [5, 6]. The frontal analysis of breakthrough curves showed a complex interaction of heat and mass fronts in fixed beds, which first was interpreted by E. WICKE [7]. The important relation between isotherm form and the adsorption energy distribution at energetic heterogeneous surfaces was pioneered by SIPS [8]. Parallel to the new multicomponent separation technology LEWIS [9] and later MYERS and PRAUSNITZ [10] developed a prediction scheme for mixtures from pure gas equilibria, which is still a standard method.

1.3. Adsorbents and Processes for Separation of Gases and Liquids

Three principle mechanisms in adsorptive separation processes can be found: steric, kinetic, and equilibrium effects. The steric effect occurs with zeolite and carbon molecular sieves (⟶ Zeolites, ⟶ Ion Exchangers). These have a very narrow distribution of micropores. Only components with critical diameter smaller than the opening of the micropores will be adsorbed. In this way, mixtures can be separated by adsorption. An example is the separation of *n*-paraffins from isoparaffins, despite its being mathematically treated as an equilibrium separation. Kinetic separation has its major application in air separation. Zeolites have a good N_2 equilibrium adsorption, but carbon molecular sieves exhibit a 30 times faster diffusion of oxygen than nitrogen. Despite the considerably lower capacities compared to zeolites the overall economics are better. However, for equilibrium separations the most vital point is sorbent selection.

Most technical-scale adsorption units typically are fixed-bed processes with multilayers. The stratified bed arrangements can be adapted well to the working ranges of several mass fronts of the various components. Therefore, the knowledge of the working capacities of the different adsorbents with respect to the various components under the given conditions of pressure and temperature are the key issue for all process design.

Three major types of processes have been established. Their names refer to the method of regeneration. The temperature swing process (TSA), the pressure swing process (PSA) or (VSA), and the concentration swing process (CSA).

Historically the TSA variant, which regenerates under elevated temperatures, was developed first in 1920. It is especially suitable where strongly bound traces must be removed from a feedstock. Compared with other desorption techniques, temperature elevation produces the highest saturation of these components in the residual gas. The high adsorption capacity for the strongly bound traces results in adsorption times that are long enough to heat and cool the adsorbers in the regeneration step of cyclic processes. Typical TSA applications are the removal of volatile organic compounds (VOC) from air (air protection) and prepurification units (PPU) in front of cryogenic air separators removing H_2O, CO_2, N_2O, and C_{3+} hydrocarbonsdown to the vol ppb level with activated alumina and molecular sieves. The total worldwide air streams to be treated with TSA PPU is about 5×10^7 m^3/h (STP) using about 10^4 t of adsorbent.

Since 1970 PSA processes have been developed that regenerate only by depressurization and low-pressure purge steps. The TSA technique is mainly suitable if more or less volatile components of balanced concentrations have to be separated at ambient temperature. With PSA, the effective saturation of the waste gas with desorbed components is acheived simply by expansion without external heat. Multidesorber systems with up to 16 vessels with various pressure-equalization steps can provide product recoveries up to 92 % for hydrogen plants, and even ultrahigh purities such as 99.999 % H_2. Examples of PSA applications are the fine purification of hydrogen from steam-reformed natural gas, refinery, and coke oven off-gas, as well as methane recovery form natural gas blends. Another application is effective separation of CO_2 and CO in steel production facilities. The worldwide production of refined H_2 of ca. 10^7 m^3/h (STP) requires 10^4 t of silica, activated carbon, and molecular sieves. When the desorption pressure is in the vacuum range, then PSA is known as the vacuum swing process (VSA). A typical application is N_2/O_2 separation from air.

If neither heat nor pressure energy is available or liquid are to be separated, desorption usually uses the CSA technique. Typical examples are VOC removal with activated carbons, hydrophobic zeolites, or adsorption polymers.

In practice, TSA, PSA, and CSA operations are not carried out in a pure form. Real processes typically use all mechanisms simultaneously. The adiabaticity of technical-scale plants always produces distinct temperature effects with ad- and desorption, even in PSA plants, and most TSA plants have additional pressure changes and pure-gas purge steps.

VOC-removal plants and PPU units can have ultrahigh throughputs of up to 5×10^5 m^3/h (STP). Then the construction is subject to extreme flow conditions, which require considerable effort for flow distribution, pressure drop, heat dissipation to and from walls, and thermal expansion of bed-limiting grids. With PPU units three major adsorber types have been established for low, medium, and high air flows: vertical, horizontal, and radial adsorbers, all which of have numerous constructive finesses to conform to actual industrial needs.

Liquid adsorption processes are expanding, with new tasks in the areas of preparative chromatography, bioadsorption, and life sciences. Here well-tailored adsorbents and customized separation units are operative. The adsorption strengths of these materials often could be conditioned by ion doping and pH control of the eluents. Relevant topics are excess isotherms, frontal analysis, computational fluid dynamics (CFD), and surface characterization. In addition to the classical fixed- and fluidized-bed processes, variants such as micellary, capillary, reactive, extractive, and gradient-oriented chromatography have been investigated for separating pharmaceutical substances, for example, enantiomers. Constructions with plates and annular adsorbers have resulted from research in this field.

The commonly applied adsorbents for technical process design of gas and liquid separations are K, Na, and Ca zeolites and Li-exchanged zeolites of the types A and X for O_2 VSA, activated carbons of various activation levels, carbon molecular sieves, activated alumina, silica of distinct porosities, and adsorber polymers. While molecular sieves, zeolites, activated alumina, and silica preferably bind polar or polarizable components, carbons and polymers prefer nonpolar molecules like hydrocarbons. By varying the inner porosity of the adsorbents they can be adapted to the volatility of the components, e.g., less volatile components need materials with larger pore radii to be well desorbable. Separation processes therefore mainly are designed as stratified beds with adsorbent layers adapted to the properties of the various components.

Activated carbon has a hydrophobic character and is especially suitable for the removal of organic substances contained in liquids (aqueous solutions) and gases. The even more hydrophobic polymeric resins are preferably used in liquid adsorption processes. New developments led to activated carbon fibers, carbon molecular sieve membranes,

and carbon nanotubes, the application potential of which is not fully exploited yet.

In general, adsorption is performed at ambient temperatures and can be tailored to any separation or purification problem with commercially available adsorbents. This makes a process very attractive and economical, even for low or nonstationary solute concentrations.

[Top of Page]

2. Adsorption Apparatus

Adsorption processes have a minimum of two steps, ie., adsorption and desorption, which define an adsorption cycle. This is true of liquid and gas adsorption despite the different physical mechanisms involved. In gas adsorption, parallel adsorption and condensation result in an adsorptions – desorption hysteresis which is not seen in liquid adsorption. Also, temperature effects in gas adsorption are more pronounced due to the additional heat of condensation and the low heat capacity. Nonisothermal operation and even safety problems (hot spots, ignition) are not seen with liquid operations, where the high heat capacity of the liquid phase guarantees isothermal operation.

A further marked difference is in the diffusivities and solubilities of the fluids involved. Diffusivities in the liquid phase are about 1000 times smaller than in the gas phase. If the solute (e.g., ethanol) is totally miscible with the process fluid (e.g., water or air) the mass of solute per cubic meter is 1000 times higher in liquid than in gas systems. However, there is a wide span of solubilities in the liquid phase, e.g., nonvolatile pharmaceuticals may have solubilities in the ppm range. Liquid adsorption and chromatography (⟶ Basic Principles of Chromatography) use similar concepts as gas phase adsorption to describe sorption in an appropriate apparatus. Chromatography also uses steric effects (gel permeation chromatography) or equilibrium solubility (partition chromatography) or chemical interactions (ion exchange or affinity chromatography) for separation.

Chromatography separates components that are injected as pulses of feed. The more weakly retained component dissolves better in the eluting mobile phase and separation is thus achieved (Fig. 1A). When the feed is pushed continuously through the column until breakthrough of the strongly adsorbed component occurs, the mode of operation is referred to as adsorption instead of chromatography (Fig. 1B)

Figure 1. Chromatographic (A) and adsorptive (B) steps

.

2.1. Gas Phase Adsorption

In gas-phase adsorption, *fixed beds* are used almost exclusively. In only a few cases are *moving* or *fluidized* beds employed. All types of bed can likewise be used in liquid-phase adsorption, although suspension mixers are also utilized in the case of finely dispersed adsorbents (e.g., powdered coal).

Fixed-Bed Adsorbers. Figure 2 shows an adsorption unit with two fixed beds. While the mixture to be purified or separated flows through the adsorber on the left, the other adsorber is being regenerated. At the start of the adsorption cycle, the incoming fluid encounters regenerated, highly active adsorbent. The adsorptive diffuses into the pores of the adsorbent. In a certain layer of the fixed bed, mass is transferred from the fluid to the solid phase. Once this layer has been saturated, succeeding mixture entering the bed flows past it into downstream layers, which then become saturated. In this way, the *mass-transfer zone* (MTZ) moves through the fixed bed with time. In this zone, the concentration of adsorptive in the fluid decreases from the feed concentration (c_0 or Y_0) to the equilibrium concentration (c_1^* or Y_1^*).

Figure 2. Adsorption unit with two fixed beds (adsorber and desorber)

Breakthrough Curves. Figure 3 shows how the effluent concentration Y_i changes with time or with the total fluid volume throughput. The mass-transfer zone separates the fixed bed into two equilibrium zones, one upstream and one downstream. Frequently, the loading curve is almost symmetrical and S-shaped in the mass-transfer zone. This means that adsorbent utilization in the MTZ is only 50 %. When the adsorptive breaks through at the end of the loading cycle, the *length of unused bed* (LUB) is just half that of the MTZ. The breakthrough curve is obtained by continuing to operate the bed until the concentration of the mixture leaving the adsorber is equal to the feed concentration. In some cases, the shape of the breakthrough curve changes little as it moves through the bed (constant pattern). In favorable cases (equilibrium favorable for adsorption, small adsorbent particle diameter), the LUB is only one-fifth to one-fourth the length of the bed; in other cases it can be substantially longer (see Chap. Kinetics).

Figure 3. Breakthrough curves in fixed bed showing mass-transfer zone (MTZ) The diagram gives effluent loading as a function of the amount of fluid or of time

Breakthrough Time. If the volume flux $\dot{V}$ of the fluid phase with feed concentration $c_{0,i}$ of adsorptive *i* is completely depleted and the unloaded mass of adsorbent *S* is thereby enriched to a loading X_i (in kilograms of adsorbate per kilogram of adsorbent), the breakthrough time t_B* is obtained from the following material balance:

$$t_B^* = \frac{SX_i}{\dot{V}c_{0,i}} \tag{2.1}$$

This breakthrough time, however, is valid only for the case of a rectangular loading profile in the bed, which is technically unattainable. Depending on the slope of the breakthrough curve, the actual breakthrough time is shorter than t_B^*. Temperature increases in the bed due to release of the heat of adsorption further decrease the breakthrough time.

Moving-Bed Adsorbers. While the mass-transfer zone moves downstream in a fixed bed, it remains stationary in a continuously operated moving bed. Because a bed height corresponding to the mass-transfer zone is sufficient, the mass of adsorbent required is less than in the fixed bed. This advantage is offset by both the higher cost of moving the solids and the concomitant abrasion. Occasionally, moving beds are operated in cross-current (Fig. 4) or cocurrent modes.

Figure 4. Single-step, crosscurrent moving-bed adsorber

Fluidized-Bed Adsorbers. Fluidized-bed adsorbers can also be operated continuously. Figure 5 shows a multistage countercurrent adsorber with an adsorption zone at the top and a regeneration zone at the bottom. Such an apparatus, for example, is suitable for drying moist air that enters at the lower end of the adsorption zone. Dry air leaves the adsorber at the upper end. The adsorbent moves continuously from top to bottom over individual trays on which fluidized beds are formed.

Figure 5. Continuous countercurrent adsorber for drying air

The loaded adsorbent, moving countercurrent to the rising hot gas, reaches the regeneration zone at the bottom and is regenerated in this way. Subsequently, solids are returned to the top pneumatically via a vertical line.

Figure 6 shows the so-called Hypersorber, which permits continuous separation of a gas mixture into its two components. The feed is injected at the middle of the column. The adsorbent moving downward from the top adsorbs one gaseous component, while the other component is drawn off as the head product. The adsorbed component leaves the adsorbent in the evaporation or regeneration zone, where the adsorbent is stripped with a hot gas or steam. Above this zone, the bottom product (the adsorbed component) is drawn off. The adsorbent leaves the apparatus at the bottom and is returned to the top pneumatically. After being recooled, it is again delivered to the adsorption zone.

Figure 6. Continuous countercurrent adsorber for separating a gas mixture

Adsorption Wheels. Vertical and horizontal adsorption wheel systems operate continuously. The adsorbent is contained in basket segments or coated onto a metal or ceramic honeycomb substrate. These structures rotate on a vertical or horizontal axis for removing the adsorbate, and a small portion of the wheel is used for thermal regeneration (Fig. 7). The advantage is the low pressure drop, whereas due to the short residence time and mechanical leakage of the seals efficiency is low.

Figure 7. Rotary adsorber

The adsorbent is regenerated by temperature or pressure swing, displacement, or extraction. The temperature swing process, which is the most common, can be achieved by indirect heating (external double jacket) or directly with hot gas or steam. If steam is used, an adsorption cycle then consists of the steps adsorption, desorption, drying, and cooling prior to fresh adsorption.

2.2. Liquid-Phase Adsorption

In liquid-phase adsorption of suspensions, fluidized beds and mixers are used in addition to fixed beds. Figure 8 shows a mixer in which mass is transferred from the liquid to the adsorbent particles suspended in it; the suspension is then separated by filtration into the purified liquid and the loaded adsorbent. A new concept for continuous adsorption are carousel adsorbers, which have their origins in ionic separations (ISEP) and liquid adsorption or chromatographic separations (CSEP) [11]. Up to 30 absorber units are installed on a rotating support disk, and flexible valve switching provides true continuous operation (Fig. 9).

Figure 8. Adsorption unit for liquid processing

Figure 9. Carousel adsorber

Figure 10 shows a three-component separation. Three or more products can be obtained, and the unit is very flexible with regard to installation of additional sanitation (usually with NaOH), regeneration (usually with an acid), or washing steps (usually with water) prior to reuse. Scrubbing, i.e., product reflux prior to desorption, is also possible to remove impurities when high-purity products are demanded. The same principle is applied in annular adsorption or chromatography. Instead of slowly rotating columns the sorbent is packed between two concentric cylinders. The feed and the eluent are continuously fed into the top of the annular bed. While the eluent is uniformly fed to the entire circumference, the feed mixture is introduced into only one sector of the annular bed. The column assembly is slowly rotated, while the feed nozzle remains stationary. Rotation causes the separated components to appear as helical bands, each of which has a characteristic, stationary exit point (see Fig. 11) [12, 13]. The result is quite similar to the ISEP principle in Figure 10, and all the features, e.g., sanitation, washing, scrubbing etc., can be applied here in a similar manner [14].

Figure 10. Carousel adsorber

Figure 11. Annular chromatography

The advantage of the ISEP principle is high flexibility. All the colums can be connected in series to obtain a simulated moving bed (SMB) configuration, as shown in Figure 12. Like in distillation, the feed is fed into the middle of the column assembly resulting in a pure component A in the enriching and B in the stripping section. In contrast to a true moving bed there is no packing attrition due to shear forces, column packing is uniform, and flow control is precise. To achieve countercurrent flow of the packing all inlet and

outlet flows are periodically shifted in the same direction to a new zone (Fig. 13). The simulated solid flow is thus directly linked to the shift period, and a triangular operating diagram has been developed [15] that allows a quasi-steady-state SMB process to be designed with flow control that depends on the sorption equilibria involved. Without this, the concentration fronts, as shown in Figure 14, will move, so either no pure A or B or even no separation would be achieved.

Figure 12. SMB carousel adsorber

Figure 13. Simulated moving bed

Figure 14. Simulated moving bed concentration profile

Zone I, desorption of A, is between the point of desorbent injection and extract withdrawal. The adsorbent entering Zone I carries only A and S. The liquid entering the top of the zone consists of pure S. As the liquid stream flows downward, component A in the pores is displaced by S. A portion of the liquid leaving the bottom of Zone I is withdrawn as extract; the remainder flows downstream into Zone II as reflux.

Zone II, desorption of B, is between the point of feed injection and extract withdrawal. At the fresh feed point, the upward flowing solid adsorbent contains the quantity of component B that was adsorbed in Zone III. However, the pores will also contain a large amount of A, because the adsorbent has just been in contact with fresh feed. The liquid entering the top of Zone II contains no B, only components A and S. Thus, component B is gradually displaced from the pores by A as the adsorbent moves up through Zone II. At the top of Zone II the pores of the adsorbent contain only A and S.

Zone III, adsorption of A, is between the point of feed injection and raffinate withdrawal. As the feed flows down through Zone III, countercurrent to the solid adsorbent flowing upward, component A is selectively adsorbed from the feed into the pores of the adsorbent. At the same time, the desorbent, component S, is desorbed from the pores of the adsorbent to the liquid stream to make room for A in the pores.

Zone IV, the isolation zone, is where the feed components in Zone III are segregated from extract in Zone I: At the top of Zone I, the adsorbent pores are completely filled with S. The liquid entering the top of Zone IV consists of B and S. By properly regulating the flow rate [15] of Zone IV it is possible to prevent the flow of component B into Zone I and avoid contamination of the extract.

In practice, it is very difficult to actually move a solid bed of adsorbent. In the Sorbex process, the countercurrent flow of liquid feed and solid adsorbent is accomplished without physical movement of the solid. Instead, countercurrent flow is simulated by periodically changing the points of liquid injection and withdrawal along a stationary bed of solid adsorbent (Fig. 15). In this simulated moving bed (SMB) technique, first patented by UOP [16], the concentration profile shown in Figure 14 actually moves down the adsorbent chamber. As the concentration profile moves, the points of injection and withdrawal of the net streams are moved along with it. This movement of the net streams is performed with a unique rotary valve developed by UOP specifically for the Sorbex family of processes.

Figure 15. Sorbex process (UOP)

a) Pump; b) Adsorbent chamber; c) Rotary valve; d) Extract column; e) Raffinate column

The flow distribution at each stage is achieved with specialized internals and grids, which are used to inject or withdraw liquid via the bed lines connecting the beds to the rotary valve. A typical unit has 12 beds and, in order to double the number of stages, two colums are then in series. At any given time, only four of the bed lines are active in carrying the net streams into and out of the adsorber. The rotary valve is used to periodically switch the position of the liquid feed and withdrawal points as the composition profile moves down the apparatus. It also sends the diluted extract and raffinate to the distillation columns and reprocesses the desorbent. A circulating pump provides a liquid flow from the bottom to the top of the column.

3. Adsorbents

The most important industrial adsorbents are oxygen-containing compounds such as silica gel, activated alumina, zeolites and molecular sieves, clay minerals, and pillared clays with hydrophilic properties, and adsorbents with carbon as the major component (activated carbon, activated coke, carbon molecular sieves, carbon nanotubes, and polymeric resins), which are hydrophobic in nature (see Table 1).

Table 1. Industrially important adsorbents

	Adsorbent	Major component	Shape* and size	True density (kg/m^3)	Apparent density (kg/m^3)	Packing density (kg/m^3)	Micropore volume (cm^3/g)	Macropore volume (cm^3/g)	Specific surface (m^2/g)	Specific heat capacity (J/kg K)	Thermal conductivity (W/m K)	Porosity ∈ (-)
Oxygen-containing adsorbents	Silica gel	SiO_2	P, S (1–8 mm)	2200	750 – 1250	300 – 850	0.30 – 1.15	< 0.10 – 0.25	100 – 850	0.92 – 1.0	0.14 – 0.20	0.45 – 0.65
	Activated alumina	Al_2O_3	G, S (2–10 mm)	3000 – 3100	1200 – 2400	700 – 950	0.40 – 0.60	0.10 – 0.15	100 – 400	0.88 – 1.05	0.12	0.13 – 0.6
	Zeolites and molecular sieves	SiO_2 Al_2O_3	P, S (1–5 mm), HC (6–7 mm), CP (2–4 mm)	2100 – 2600	1100 – 1500	400 – 900	0.20 – 0.30	0.30 – 0.70	350 – 1100	0.80 – 1.05	0.13 – 0.58	0.5 – 0.6
	MCM	SiO_2 Al_2O_3	HC		550 (min)	170 – 450	Mesopore: 0.21 – 1.00	450 – 1200			0.20 – 0.52	
	Clay mineral	SiO_2 Al_2O_3	P, G	2200	1600 – 1700	500 – 700	~ 150	0.19 – 0.40	120 – 500			0.20 – 0.35

	and pillared clays											
Carbon adsorbents	Activated carbon	C	P, G (1–10 mm), CP	1880 – 2200	440 – 900	250 – 550	0.20 – 0.50	0.40 – 1.5	200 – 4000	0.76 – 0.92	0.65 – 0.1	0.45 – 0.77
	Activated coke	C	P, G	~ 1900	~ 900	450 – 600	0.01 – 0.10	0.20 – 0.30	15 – 400			~ 0.35
	Carbon molecular sieves	C	P, S, CP	1800 – 2100	900 – 1290	600 – 900	~ 0.18	0.38 – 0.60	100 – 1500	0.84 – 1.00	0.65	0.35 – 0.57
	Carbon nanotubes	C	P				Mesopore: 0.05 – 0.45	150 – 650				
	Polymeric resins	C, H	S, G	1000 – 1300	400 – 900	300 – 750	< 0.10 – 0.43	0.37 – 1.50	80 – 1500	0.33 – 1.5**	0.06 – 0.07**	0.35 – 0.65
Π - Complexation sorbents		SiO_2, C, Cu, Ag	P, G, CP					0.20 – 1.60	50 – 670			

*P: fine powder; S: spheres; G: granules; HC: hollow cylinder (external diameter); CP: cylindrical pellets (diameter)
**In dry state

Adsorbate – Adsorbent Interactions. The adsorbate – adsorbent interactions are of threefold nature: dispersion, electrostatic, and chemical bonding. Polarizability, magnetic susceptibility, permanent dipole moment, and quadrupole moment of the solute decide the selection of the adsorbent. With activated carbon nonspecific van der Waals (dispersion) interactions dominate, and thus they preferentially accumulate organic substances and nonpolar adsorptives with high polarizability and magnetic susceptibility and low polarity. If the solute has a high dipole or quadrupole moment highly polar (hydrophobic) surfaces are needed. For ultrapurification a strong (chemical) bond results in a high Henry constant. Pore size and surface characteristics determining the interactions are created in the sorbent preparation process, which is discussed in detail in [17].

The selection of a sorbent from a practical point of view are determined by the following criteria:

1. Capacity of the sorbent
2. Product purity or selectivity
3. Regeneration method (pressure or thermal swing)
4. Length of unused bed (LUB)
5. Price

Capacity and selectivity are a matter of the equilibrium isotherms discussed in Chapter Thermodynamics, Equilibria, and Heat of Adsorption. The equilibrium isotherms of all constituents in the mixture must be considered, and in a simplified approach the isotherms of pure components may be regarded as additive to obtain the multicomponent adsorption behavior. The LUB is approximately one-half of the span of the mass transfer zone and is primarily determined by the equilibrium isotherm. A sharp concentration front (short LUB) results from a high sorbent productivity and gives a high product purity. This is associated with a higher price, which can be paid for bulk separations and is more critical for purification processes. Here bulk separation refers to separations of a mixture with adsorptive concentrations higher than 10 %.

Particle size influences mass transfer, pressure loss, and operability. Small particles have a shorter intraparticle diffusion path and thus promote diffusion and mass transfer, but they result in a higher pressure loss. Particle sizes for gas-phase processes range from 1 to 10 mm, while liquid-phase applications use smaller diameters due to lower liquid diffusivities. Generally, adsorbents are used in the form of spheres, rods, or moldings. Here spherical particles are more expensive than angular ones resulting from crushing and sieving of larger blocks. The latter tend to produce fines which affect pressure drop and result in a more troublesome operation. Adsorbents for moving or fluidized beds must exhibit high abrasion resistance, which depends on particle shape and hardness.

For determination of a particle size distribution established methods are available [18]. However, care should be taken in their measurement and presentation. In a number distribution the smaller particles will be dominant, whereas in a volume or mass distribution the larger ones will prevail.

Density and Porosity. A distinction is made between the solid particle density (the true density of the material), the apparent density of a grain with pores, and the bulk density of the packing in a fixed-bed adsorber (see Table 1).

The true density is the quotient of mass of dry adsorbent and the volume of the solid phase.

$$\rho = \frac{m_p}{V_m} \tag{3.1}$$

The true density can be estimated by pycnometric methods using helium or methanol [19, 20].

The apparent density includes the volume of the pores

$$\rho_s = \frac{m_p}{V_m + V_{Pore}} \tag{3.2}$$

and can be determined by mercury pycnometry [20] or by weighing [21]. The porosity of a particle is then [19]

$$\varepsilon_p = 1 - \frac{\rho_s}{\rho} \tag{3.3}$$

The density of a packed bed [19, 22] determines the voidage or bed porosity:

$$\varepsilon_B = 1 - \frac{\rho_B}{\rho_s} \tag{3.4}$$

It can be determined from a residence-time experiment with a tracer which cannot enter the pores. In liquid applications the retention time $t_{\in}$ of, e.g., Dextran blue (molecular weight ca. 2×10^6), the flow rate V, and the total column volume V_C, give:

$$\varepsilon_B = \frac{t_s \cdot V}{V_C} \tag{3.5}$$

In general, $\in_B$ lies between 0.33 and 0.5. If a nonretained (nonadsorbable) tracer is available that is small enough to diffuse into the pores, the inner porosity $\in_p$, can also be determined. From the peak maximum of the small tracer the total porosity is determined

$$\varepsilon_t = \frac{t_p \cdot V}{V_C} \tag{3.6}$$

and the inner porosity can be calculated:

$$\varepsilon_t = \varepsilon_B + (1 - \varepsilon_B) \cdot \varepsilon_p \tag{3.7}$$

The most important characteristics of a sorbent is its high *specific internal surface area a*. It is inversely proportional to the mean pore diameter. Thus, the molecular size of the adsorptive determines the minimal pore diameter accessible for penetration. The standard technique to evaluate the surface area of a sorbent is the BET method [23]. The BET equation is used to calculate the amount of N_2 for monolayer coverage at 77 K. For activated carbon a simpler method using iodine [24] results in an equivalent iodine number (mg/g), which is usually in good accordance with BET measurements [25].

Pore Size Distribution. A grain is permeated by many pores of different width. The system of pores in an adsorbent particle may contain *submicropores* (< 0.4 nm) *micropores* (< 2 nm), *mesopores* (between 2 and 50 nm), and *macropores* (> 50 nm) [26, 27]. Some adsorbents (e.g., zeolitic molecular sieves) have a well-developed bimodal pore-size distribution so that the total pore volume consists of the volume of micropores and macropores.

The total pore volume and its distribution over the pore diameter characterizes the pore volume. Macro- and mesopores are determined by mercury porosimetry [28] or nitrogen adsorption [29], while micropores are estimated by molecular sieving [30]. All these techniques are widely discussed elsewhere [23, 31, 32]. Many adsorptives have broad pore size distributions, with macro- and mesopores for transport, and micropores for adsorption. A large micropore volume leads to a high specific internal surface available for accumulation of adsorptive. Specific surface areas are between 200 and 1800 m^2/g. A survey from simple to fractal pore models is given in [33]. There is an influence on sorption equilibria, hysteresis, and capillary condensation (see Chap. Thermodynamics, Equilibria, and Heat of Adsorption) and a further impact is on intraparticle diffusion, depending on pore size and tortuosity (see Chap. Kinetics).

Specific heat capacity and thermal conductivity (Table 1) are important if the bed of an adsorber is heated during loading by the heat of adsorption or if it is to be regenerated by heating in a temperature swing process.

Thermal stability is very important in industrial applications. Zeolite molecular sieves can withstand a maximum temperature of 800 °C, but with silica gel and aluminum oxide, the risk of damage begins above 300 °C.

Chemical Resistance. Small amounts of acid can damage aluminum oxide, but this adsorbent is insensitive to alkali. Adsorbents containing carbon are highly resistant to acid, except for oxidizing acids above ca. 400 °C. Chemically neutral silica gel is unaffected by acids except for aqueous hydrogen fluoride, but it is attacked by alkali. Polymerizable materials may plug the pores (see Section Separation of Nonaqueous Substances). Zeolitic molecular sieves are chemically resistant in the pH range 5 – 12.

Porous glass of various types can be used as adsorbents if organic acids are to be dried by adsorption, even though they exhibit neither the narrow micropore distribution nor the adsorption capacity of zeolites. Both their selectivity and their capacity are therefore poorer.

Aging of adsorbents may occur due to irreversible changes in structure at elevated temperature or plugging of pores by impurities and reaction products, (e.g., polymers). Such aging reduces both the adsorption capacity and the pore diffusion coefficient. Reactivation (see Section Reactivation of Adsorbents) involves a loss of capacity.

3.1. Oxidic Hydrophilic Adsorbents

Oxidic hydrophilic adsorbents such as silica gel, activated alumina (activated aluminum oxide), and zeolitic molecular sieves preferably adsorb polar adsorptives.

Activated Alumina. The surface and pore structure of aluminates or activated alumina can be controlled during the activation process and by using dopants [34]. The surface acidity is due either to Brønsted acid sites (i.e., OH groups that release protons) or Lewis acid sites (sites which can accept electrons). Due to the attractive price (ca. 1.5 €/kg) they are used in wastewater treatment and water purification. Removal of arsine, phosphate, chloride, and fluoride in water treatment has been reported [35]. They are very hydrophilic and are used in the liquid phase for drying of organics such as gasoline, cyclohexane, refrigerants, and lubricants [36].

In the gas-phase activated alumina is widely used for desiccation since it has higher capacity for water than zeolites. However, there is major competition with molecular sieves, which have high capacities at low vapor pressures. A further application is to remove acid gases such as HCl and HF from air and COS, CO_2, H_2S, and CS_2 from hydrocarbons. They are attractive for polar Lewis bases in the following order: aromatic and halogenated hydrocarbons < ethers, esters, ketones < amines, alcohols < carboxylic acids [37]. Impregnation of activated alumina with alkali metal oxides (i.e. K_2O, Na_2O, NH_4OH) yields alkalized alumina, which is used commercially for flue gas desulfurization [38]. CO_2 removal down to the 1 ppm level [39] and NO/NO_2 separation [40] are novel areas, whereas a traditionally wide application is as support material in catalysis.

Silica gel (⟶ Silica – Colloidal Silica) is composed of silicon dioxide and water (up to 40 %). Once water has been removed from silica gel, it exhibits a high adsorption capacity for water and other polar substances. Commercial silica gels are mesoporous with a pore size larger than 2 nm. The structure is a network of silicon atoms connected by oxygen atoms. The surface is saturated with hydroxyl groups, and the silanol number refers to the OH density (nm^{-2}). The high hydrogen-bonding capability of water with the OH groups makes silica gel an ideal desiccant. Silica gel doped with $CoCl_2$ changes color from blue to pink with increasing moisture content. Substances other than water, such as esters, ketones, ethers, and nitrogen-containing compounds (NH_3, amines, pyridines, etc.) that have hydrogen-bonding abilities can be adsorbed in a similar way. Silica gels can be easily regenerated by temperature swing (at about 150 °C) and are rather cheap materials (0.5 – 2 €/kg). To make the originally polar surface apolar, it is modified by grafting with a monomolecular layer of an organic ligand. The resulting materials have wide application in reversed-phase chromatography [41, 42], where most of the interactions are then reversed compared to pure silica.

Grafting agents for silica include various silanes [17, 43], of which 3-aminopropyltriethoxysilane is the most commonly used. Amine-grafted silicas adsorb CO_2 and H_2S rapidly with high capacities and are promising sorbents for selective adsorption in fields such as catalysis and environmental protection [17]. Molecularly imprinted microporous silica is applied in biosciences, e.g., for separation of racemates, but suffers from very low capacities [44].

Zeolites (⟶ Zeolites) are natural or synthetic crystalline aluminosilicates of alkali (x=2) or alkaline earth metals (x=1) with the stoichiometry: $M_xO{\cdot}Al_2O_3{\cdot}y\ SiO_2{\cdot}z\ H_2O$.

Zeolite crystals consist of SiO_4 and AlO_4 tetrahedra. By linking these polyhedra via four-, six-, eight-, and twelve-membered oxygen rings, cavities are formed which extend over the entire zeolite crystal. Figure 16 shows widely used zeolites, type A, type X, and type Y. In principle, a distinction is made between the larger α-cages and the smaller β-cages.

Each aluminum atom contributes a negative charge to the crystal structure, which must be offset by a cation. The cations (K^+, Li^+, Na^+, Ca^{2+}) can be exchanged during the manufacturing process and determine the channel diameter of the zeolite cage.

Type 5A (Ca^{2+} cation) has a channel diameter of about 0.43 nm, while the channel diameter of type 10X (Na^+ cation) is ca. 0.74 nm. Depending on the type of zeolite and the diameter of the exchanged ions, the channel diameter of the cages can be tailored to permit only molecules with smaller diameters to enter. This produces a sieve effect, hence the name “molecular sieve”. Table 2 gives an overview of some industrially important zeolites and their effective channel diameters. In addition, some areas of application are listed.

Figure 16. Cage structure of zeolitic molecular sieves

A. Type A zeolite: a) α-cage, diameter 1.14 nm, opening ca. 0.43 nm; b) Structure of type A; c) Truncated octahedron, β-cage, diameter 0.66 nm, opening 0.25 nm
B. Type X and Y zeolite: a) Largest cavity, diameter 1.16 nm, opening 0.74 nm; b) Structure of types X and Y

Table 2. Industrially important zeolites and their effective channel diameters [133]

Framework	Critationic form	Formula of typical unit cell	Window	Effective channel diameter, nm	Application
A	Na^+	$Na_{12}[(AlO_2)_{12}(SiO_2)_{12}]$	8-ring (obstructed)	0.38	desiccant, CO_2 removal from natural gas
A	Ca^{2+}	$Ca_5Na_2[(AlO_2)_{12}(SiO2)_{12}]$	8-ring (free)	0.44	linear alkane separation, air separation
A	K^+	$K_{12}[(AlO_2)_{12}(SiO_2)_{12}]$	8-ring (obstructed)	0.29	drying of cracked gas containing C_2H_4 , etc.
X	Na+	$Na_{86}[(AlO_2)_{86}(SiO_2)_{106}]$	12-ring	0.84	pressure-swing H_2 purification
X	Ca^{2+}	$Ca_{40}Na_6[(AlO_2)_{86}(SiO$	12-ring	0.80	removal of mercaptans from natural gas

		$_2)_{106}]$			
X	Sr^{2+}, *Ba^{2+}	$Sr_{21}Ba_{22}[(AlO_2)_{86}(SiO_2)_{106}]$	12-ring	0.80	xylene separation
Y	Na+	$Na_{56}[(AlO_2)_{56}(SiO_2)_{136}]$	12-ring	0.80	xylene separation
Y	K^+	$K_{5+}[(AlO_2)_{56}(SiO_2)_{136}]$	12-ring	0.80	xylene separation
Mordenite	Ag^+	$Ag_8[(AlO_2)_8(SiO_2)_{40}]$	12-ring	0.70	iodine and krypton removal
Mordenite	H^+	$H_8[(AlO_2)_8(SiO_2)_{40}]$			from nuclear off-gases
Silicalite		$(SiO_2)_{96}$	10-ring	0.60	removal of organic chemicals from water
ZSM-5	Na +	$Na_3[(AlO_2)_3(SiO_2)_{93}]$	10-ring	0.60	xylene separation

*Also K·BaX, where X = zeolite anion.

Thus, the effective channel diameter of the zeolite cages determines, during adsorptive separation on molecular sieves, whether or not a molecule having a certain critical molecular diameter can diffuse into the cage and be adsorbed there. Critical molecular diameters for some inorganic and organic substances are given in Table 3.

Table 3. Critical molecular diameters and molecular sieves suitable for adsorption on the basis of pore size

Molecule	Critical diameter, nm	Adsorption by 3 A	4 A	5A	10 X or 13X
He	0.2	x	x	x	x
Ne	0.32		x	x	x

*(x) = suitable

The manufacturing process for zeolites leads to a bimodal distribution of pore radii typical of oxidic adsorbents. The differential distribution of pore radii in oxidic adsorbents is shown in Figure 17. Molecular sieves exhibit two clearly developed maxima: one for micropores with a radius of 0.2 – 0.3 nm and another in the macropore range at ca. 300 nm. The macropores are interspersed between individual microcrystals. They have a very small specific surface and hence a negligible adsorption capacity. Nevertheless, diffusion in the macropores often determines the rate of sorption (see Chap. Kinetics).

Figure 17. Distribution of pore radii in oxidic adsorbents

The most commonly used zeolites and molecular sieves in adsorption and ion exchange are the types A, X, and Y. However, by substituting other elements for Al and/or Si an infinite number of molecular sieves (which are formally not zeolites) can be created. This is of interest for catalysis or petrochemical industry, when for instance $[TiO_h]$ provides oxidation sites for redox reactions [17, 45]. While Linde's interest was in the development of new sorbents (zeolites A, X, and Y), Mobil was more interested in catalysis when developing the ZSM zeolites, the most useful of which is ZSM-5, prepared by using amine templates to produce zeolite crystals of a specific channel diameter [45]. Linde independently developed a similar zeolite, called silicalite [46], in which both channel sizes are comparable to the size of many important solutes such as *n*-paraffins, isoparaffins, aromatics, and their derivatives.

A high aluminum content promotes adsorption of polar components. Dealuminated Y zeolites (DAY) are more hydrophilic and have a higher affinity for nonpolar organic

substances from wet exhaust gases [47]. Zeolites do not burn and are stable up to 700 – 1000 °C, which can be used for cleaning purposes [48]. They are not inert against acidic attack, but a higher silicon content improves resistance against strong acids but make it worse against strong bases [49]. Generally speaking, the relatively high price of zeolites of 1 – 4€/kg makes them largely suitable for applications in special gas separation processes, and their use as desiccants is not really promising due to the high regeneration temperatures of about 350 °C.

By using quaternary ammonium surfactants as templates, it was possible to synthese a new family of ordered, mesoporous silicates or aluminosilicates. MCM-41 is the best known and has a simple structure due to the rod-type hexagonal array of cylindrical micelles. The silicate precursors condense on the wall of the templates, which are subsequently removed by oxidation to leave behind a honeycomblike structure. Despite the uniform pore structure and pore sizes of up to 30 nm, application in adsorption is not likely owing to the high price and low capacities. However, in modified forms it may be interesting for niche applications. Metal recovery from waste waters with thiol-grafted MCM-41 has been reported [50]; regeneration is possible with HCl.

Pillared Clays. Pillared interlayered clays (PILCs) are aluminosilicates with cations and a two-dimentional layer structure. The basis is montmorillonite with a ratio of silicic acid to clay of 4:1, like bentonite. Each layer consists of a core alumina layer surrounded above and below by silica (Fig. 18). These layers are then sandwiched with pillars of metal oxide. The pore sizes in the PILCs are not limited by the interlayer spacing but by the interpillar spacing [51]. Pore sizes are near 0.4 and 0.6 nm and can be controlled and tailored with potential applications as molecular sieves [36]. They are considerably less hydrophobic than zeolites, silica gel, and activated alumina [52]. The attractive price of 1 – 1.5 €/kg promotes application in raffination of sweet oil, mineral oil, oil residues, and wastewaters.

Figure 18. Montmorillonite crystal structure

3.2. Carbon-Containing Adsorbents

Carbon-containing adsorbents such as activated carbon, activated coke, and carbon molecular sieves (⟶ Carbon – Activated Carbon) are highly porous solids which, because of their surface properties, preferentially accumulate organic substances and nonpolar adsorptives. Their amorphous skeleton consists of microcrystallites with a graphite lattice. Carbon adsorbents are produced from organic materials such as wood, peat, coal, and petroleum coke. During manufacture, the particles are first formed, then carbonized at low temperature, and finally activated (⟶ Carbon – Activating Furnaces). Activated carbon is used in the form of grains (usually for adsorption in the gaseous phase) or powder (usually in liquid-phase adsorption). Carbon-containing granular adsorbents are generally produced in extruders and sold in cylindrical shape. Pellets and crushed granules are also available.

Activated carbon fibers (ACFs) have been commercially available for gas-phase applications since the 1960s. They have high surface areas (1000 – 2000m^3/g), narrow and uniform pore size distribution, and are graphitic and elastic. Their advantage is in a high mass-transfer rate and the possibility of electrothermal regeneration. The graphitic nature makes ACFs heat resistant, so they are inflammable up to 1000 °C. Also the lack of fines and the high tensile strength of the fibers is an advantage in use. However, so far only mats are available due to problems in final tailoring, and the high price (ca. 200 €/kg) only allows special applications. Comprehensive reviews on ACFs are given in [53, 54].

Activated carbon is characterized by large surface areas of between 300 and 4000 m^2/g, which exceed those of all other sorbents (see Table 1). It has a polymodal pore size distribution, whereby microporosity (1 – 2.5 nm) prevails in gas-phase, and mesoporosity (> 3 nm) in liquid-phase applications. The specific micropore volume of activated carbon, i.e., the specific volume of pores smaller than 2 nm, is about 0.25 – 0.4 cm^3/g (see Table 1). This shows clearly that the adsorption capacity of activated carbon is determined almost exclusively by the micropores and their volume.

Figure 19 shows the distribution of pore radii in activated carbon, activated coke, and carbon molecular sieves. The carbon-containing adsorbents are distinguished by different pore sizes in the micropore range. For activated carbon, the maximum is at about 0.8 – 1 nm; for activated coke, between 0.5 and 0.7 nm, and for carbon molecular sieves, between 0.2 and 0.3 nm. This means that neither activated carbon nor activated coke is capable in practice of adsorbing only molecules below a certain molecular diameter.

Figure 19. Distributions of pore radii in carbon adsorbents

The surface of activated carbon is nonpolar or slightly polar as a result of acidic surface oxide groups and inorganic impurities. They exhibit van der Waals interactions (i.e., dispersion and expulsion forces) with the solute. The electrical charges are too weak to contribute significantly to the adsorption process. The low heat of adsorption makes stripping of adsorbed molecules relatively easy, and hence energy requirements for regeneration are low. Aromatic adsorptives are much better adsorbed than aliphatic ones, due to higher van der Waals interactions of the π-electron system. In general, adsorption capacity for carboxylic acids, alcohols, and esters increases with increasing polarity.

The hydrophobic nature of activated carbon makes it as an ideal adsorbent for treatment of wet gaseous feed streams. The adsorption of moisture is generally low, but at humidities higher than 40 % water sorption due to capillary condensation is found.

The applications of activated carbon can be extended by impregnating it with Ag, Cu, S, Zn, or I for specific recovery of a certain solute, e.g., H_2S from an CS_2/H_2S mixture with I impregnation [55]. A disadvantage of activated carbon is its low mechanical and abrasion stability. Operation in moving or fluidized beds therefore needs the harder activated coals. Besides this, SO_2 in a gas stream may oxidize carbon resulting in H_2SO_4 and “glued” activated carbon pellets, which results in inhomogeneous gas flow in the bed. Generally, inhomogenities hinder the convective transport of the heat released by adsorption and thus result in hot spots which, when they exceed the carbon ignition temperature, cause fires [56, 57].

The broad applicability of activated carbons and their attractive price of 0.25 – 2 €/kg make them the leader in worldwide sales [58]. They also have broad applications in adsorption from liquid solutions, e.g., decolorization of sugar, fruit juice, chemicals, treatment of potable water and wastewater, gold recovery in the mining industry, etc. Adsorption from liquids is more complicated than from the gas phase, since the ternary solute – solvent – adsorbent interaction is now involved. For a series of environmentally harmful substances (phenolic, aromatic, and chlorinated aromatic compounds, organic pesticides, carbon tetrachloride and other volatile organic compounds (VOC), and metal ions), isotherms are available in [59].

Carbon molecular sieves (CMS) have a mean pore diameter of 0.3 – 0.9 nm, on the same order of the magnitude of the critical molecule size of small molecules (Table 1). The distribution of the micropore radii in a CMS is not as narrow as in a ZMS, but they have the same properties towards water as activated carbons. They are made from anthracite and hard coal by partial oxidation and subsequent thermal treatment. Thermal treatment, in this case, means the thermal decomposition of synthetic polymers [e.g., polyethylene, poly(vinyl chloride), poly(vinylidene chloride)]. This treatment creates micropores with a relatively narrow distribution of pore radii. The pore structure can be modified to a certain extent by repeated thermal treatment, e.g., controlled cracking of hydrocarbons in the micropores and partial gasification.

The main use of CMS is in separation processes involving wet gas streams. Since they have no cations they are even more hydrophobic than activated carbon. The dominant use is in PSA processes (see Chap. Gas Phase Processes) where kinetic separation of N_2/O_2, ethylene/ethane or CH_4/CO_2 are performed. The last-named is is used for landfill gas with about 50 % CO_2 and tertiary oil recovery with around 80 % CO_2 [60]. They show excellent separation properties (selectivity, permeability) and high stability (chemical and thermal) and often have the advantage of operating in a harmful environment [61]. However, research in this field is just beyond the initial stages [62] and not all the drawbacks have been solved yet [63].

Further promising types of new sorbents are fullerenes and carbon nanotubes [64] with potential applications in hydrogen storage. The surface of the nanotubes contains a high density of π electrons and is highly aromatic. The nanotubes are therefore highly graphitic and it is expected that carbon nanotubes will adsorb molecules more strongly than activated carbons [63].

Polymeric resins are synthetic porous polymers with a large internal surface; their main application is in liquid adsorption. The raw materials are styrene, divinylbenzene, and acrylates. The macroporous polymeric resins can be further treated to attach functional groups to generate resins for ion exchange and chromatography (⟶ Ion Exchangers).

Polymeric resins have similar adsorption characteristics to activated carbon and are of high mechanical stability, but they swell in nonaqueous solvents [65, 66]. They are chemically stable at high pH values, and despite their 3 – 5 times higher price relative to activated carbon, they are dominant in liquid sorption processes. They can remove aromatic or chlorinated hydrocarbons, phenols, and pesticides from wastewater [67] and find a broad application in the food and pharmaceutical fields [37] for the purification of vitamins, antibiotics, and food products (sugars, fruit juices, dairy products, amino acids).

3.3. Chemical Complexing Sorbents

Traditional adsorption of solutes uses van der Waals or/and electrostatic interactions. For separation of ultrapure components, chemical bonds offer stronger and more specific interactions. A large variety of stationary sorbent phases are available serving different needs with respect to capacity and selectivity [17]. In addition, (monolayer-) impregnated porous substrates offer further applications. Supported monolayer salts and metal oxides, such as CuCl on activated carbon or alumina, have been commercially used for CO_2 recovery and separation [62], and Cu^+- and Ag^+-impregnated zeolites are, e.g,. used to remove dienes from olefins [68]. A further approach is to impregnate porous support materials with liquid ion exchangers, which are cheap and readily available. Cation, anion, chelating, and neutral liquid ion exchangers can be used; the chemistry is discussed elsewhere [69, 70]. Despite the fact that the liquid ion exchangers are only physically adsorbed on the support material, bleeding in liquid adsorption processes is negligible [71]. The main application is to remove traces of heavy metals such as Zn, Cu, Pb, and Cd from effluents, [72, 73]. However, large-scale applications have not been reported so far, which gives prospects to applications in new fields [74].

[Top of Page]

4. Thermodynamics, Equilibria, and Heat of Adsorption

The basic approach to adsorptive equilibria, i.e., loading versus partial pressure, must provide a suitable description of both the equation of state for the fluid phase and the adsorption energy levels due to the various adsorption sites involved. The knowledge of the distribution of the molecules in the fluid phase and on the adsorption sites is the key issue in understanding and describing adsorptive equilibria. Statistical considerations lead to an occupation index for each individual site, dependent on the chemical potential of the gas phase, i.e., its pressure and temperature. However, the statistical approach is different for surface adsorption with only one molecule per energy level (Fermi – Dirac case, isotherm type I), with a restricted number of adsorbed molecules per energy level (BET isotherm types II, IV) and with pore condensation (Bose – Einstein case, isotherm types III, V). Each approach exhibits a characteristic picture for adsorption isotherms, as is apparent in the IUPAC classification of types (Fig. 20).

An ideal pure gas is defined by two parameters: pressure p and temperature T. The energetically homogeneous surface is described by two adsorption parameters, the adsorption energy level μ_a and saturation loading q_0 (equivalent to the specific surface area). The equilibrium condition between fluid and adsorbed phase reduces the four independent parameters to three (Gibbs –Duhem relation). The appropriate homogeneous three-parameter equation was derived by LANGMUIR [2]. Equilibria with real gases have two further fugacity parameters (critical pressure and temperature), while real surfaces with energetic heterogeneities are best approached by a suitable energy distribution of sites in connection with a further parameter characterizing the distribution energy width. Hence, typical adsorption equilibria for an ideal gas phase but a heterogeneous adsorbent are four-parameter equations like the Toth, Unilan, Langmuir – Freundlich, and Dubinin relations [6, 8, 75, 76]. To take account of condensation effects, parameters for liquid properties are necessary, as in, e.g., the BET and the Ruthven equations [4, 77].

In practice some caution is advisable if condensation can not be excluded in an adsorption processes because of conditions in the vicinity of the dew point. Then effective regeneration is thwarted by hysteresis effects due to the loss of the surface degree of freedom.

Figure 20. Various types of adsorption isotherms

4.1. Explicit Equilibria

The basic variables to describe adsorption equilibria are the fluid partial pressure p_i (or fugacity f_i for real-gas conditions) for each component i, the temperature T, the fractional surface (monolayer) coverage $\Theta_i=q_i/q_{0i}$ and the adsorptive vapor pressure Φ_i at the standardized condition Θ_i=1/2 (adsorptive saturation pressure). Here q_i and q_{0i} are equilibrium and saturation loading. With condensable components also the liquid saturation pressure Φ_{Li} is important, as well as the relation of liquid to adsorptive gas phase saturation pressure $b_i= \Phi_{Li}/ \Phi_i$. The fractional volumetric loading V_i/V_{is} accounts for the relative pore filling with respect to the entire pore volume available for wetting, which typically is 3 – 5 times the volume surface coverage. Figure 21 shows an isotherm exhibiting surface coverage, pore filling, and condensation. Figure 22 presents water and n-hexane isotherms on several porous adsorbents.

4.1.1. *Single-Component Pure-Gas Equilibria*

Homogeneous Surfaces. Under the condition that all adsorption sites are energetically homogeneous with adsorption enthalpy H_a and each site can be occupied by one or no molecule the Langmuir equation [3] holds

$$\Theta = \frac{q}{q_0} = \frac{1}{1+\phi/p} \tag{4.1}$$

where the surface adsorption saturation pressure

$$\phi = p_0 e^{A-H_a/(RT)} \tag{4.2}$$

is of *Arrhenius* form. This reference pressure at the condition Θ=1/2 normally is about three orders of magnitude smaller than the corresponding liquid saturation Φ_L at pore condensation with vapors. The surface adsorption saturation pressure Φ can be calculated from Φ_0, given for a reference temperature T_0 as

$$\phi = \phi_0 e^{(H_a/R)(1/T_0-1/T)} \tag{4.3}$$

The Langmuir equation can be transformed into

$$\frac{\Theta}{1-\Theta} = \frac{p}{\phi} \tag{4.4}$$

with the point of symmetry Θ=1/2 and $p= \Phi$. In the low-coverage range the Langmuir equation approaches the Henry equation

$$q = hp \tag{4.5}$$

where $h=q_0/ \Phi$ is the Henry constant obeying the van't Hoff equation

$$R\frac{\partial \ln(h/h_0)}{\partial(1/T)} = H_a \tag{4.6}$$

where h_0 is the Henry constant at a reference temperature T_0. The isosteric equilibrium pressure p corresponds to the Clausius – Clapeyron relation

$$\left(\frac{\partial p}{\partial T}\right)_{q=\text{const}} = \frac{pH_a}{RT^2} \tag{4.7}$$

The Langmuir equation has three independent parameters: q_0, Φ_0, and H_a.

Heterogeneous Surfaces. If, instead of a narrow distribution of adsorption site energies peaking at H_a, the adsorbent has a broadened distribution with variance $\in$ the isotherms are flattened near Θ=1/2. The equilibrium isotherm then must be calculated by an integral, weighting the homogeneous equilibria for each energy level with the energy distribution function. From the manifold of known approaches, each related to a certain energy distribution function, the discussion is restricted here to two major representations: the uniform and the hyperbolic energy distributions, which result in the UniLan and the GM equations.

The *UniLan equation* [76] is related to a rectangular energy distribution within the range of $H_a \pm \in$

$$\Theta = \frac{RT}{2\varepsilon} \ln \frac{1 + \left[p/\phi\right] e^{\varepsilon/(RT)}}{1 + \left[p/\phi\right] e^{-\varepsilon/(RT)}} \tag{4.8}$$

At higher temperatures $T > \in/R$ the UniLan equation approaches exactly the Langmuir equation for the homogeneous case.

The second practical equation for heterogeneous surfaces is based on the smoother hyperbolic distribution $1/[\in(2 + e^{\omega} + e^{-\omega})]$ where $\omega = (H - H_a)/\in$, presenting a Gaussian-like shape of broadness $4\in$, but with an exponential decay. The approximately related *GM isotherm* [78, 79] is of the form

$$\Theta = 1/\left\{1 + [\phi/p]^{a(T)}\right\} \tag{4.9}$$

where

$$a(T) = RT/\varepsilon \quad \text{if } RT < \varepsilon \quad \text{and } a(T) = 1 \quad \text{elsewhere} \tag{4.10}$$

This equation is of the Langmuir – Freundlich type but includes distinct temperature dependence of the exponent $a(T)$. Again, for $T > \in/R$ the equation approaches the Langmuir equation. High-accuracy modifications of Equation (4.10) use $a(T) = 1/[m + \in/(RT)]$ where m is an adjustable parameter [78]. Thus, homogeneity or heterogeneity is not simply a question of the absolute broadness of the distribution $\in$ of the adsorption energy level, but is defined by the ratio of $\in$ and the thermal fluctuation RT. At higher temperatures the adsorbent's heterogeneity is overridden by thermal fluctuations filling all surface sites simultaneously. The result then resembles a homogeneous situation, where the adsorption energy distribution is narrow with respect to RT.

With the UniLan and GM equations, the homogeneous isotherm parameters q_0, Φ_0, and H_a are supplemented by a fourth independent parameter: the energetic heterogeneity $\in$ of the site distribution. Table 4 lists some examples for molecular sieve 5A. Figures 23-25 present methane, ethane, and propane isotherms on activated carbon. They show an increasing curvature (nonideality) with increasing C-number. Therefore the appropriate approximations are the UniLan or GM-equation. Figures 26 and 27 show the strongly nonideal water and CO_2 isotherms on molecular sieve 5A.

Table 4. Equilibrium parameters for several components at molecular sieve 5A using the UniLan approximation (Eq. 4.8) at T_0 = 273.15 K. For comparison: RT_0 = 2.27 kJ/mol.

Component	q_0 (0 °C), mol/kg	H_a, kJ/mol	$\in$, kJ/mol	Φ_0 (0 °C), bar

Homogeneous Surface with Additional Multilayer Pore Condensation. If the first (surface) layer is adsorbed with uniform enthalpy H_a and the second to the *N*th layer are condensed with liquefication enthalpy H_L the equilibrium is represented by the BET equation [4] by using $\varphi = p/\Phi_L$, $b = \Phi/\Phi_L$, and $\Phi_L = p_0 e^{A-H_L/(RT)}$

$$\Theta = \frac{b\varphi}{1-\varphi}\,\frac{1-(N+1)\varphi^N + N\varphi^{N+1}}{1+(b-1)\varphi - b\varphi^{N+1}} \tag{4.11}$$

Here $\Theta = q/q_{0mon}$ is related to monolayer saturation loading q_{0mon}. For N=1 the equation results in the Langmuir formula. The equation is widely used to determine the BET surface area.

Vapors. For condensable components DUBININ found a correlation of adsorptive equilibria at various temperatures and for similar components via the Polanyi binding potential [1]

$$\mu_b = \mu_a - \mu_L = -RT \ln (p/\phi_L)\,, \tag{4.12}$$

where μ_a and μ_L are adsorption and liquefaction energies. With the pore filling volume

$$V = q v_m \tag{4.13}$$

where v_m is the liquid molar volume (cm^3/mol) under standard conditions (e.g., vapor pressure of 1 bar), the general Lewis correlation is

$$V = F(\mu_b/\beta) \tag{4.14}$$

with an experimentally fitted function *F* and an affinity coefficient β. The affinity coefficient was taken by *Lewis* as $\beta = v_m$ [9]. From that, DUBININ assumed a Gaussian-like energy distribution, leading to an isotherm [5, 6]

$$\Theta = \exp\{-(\mu_b/\varepsilon)^a\} = \exp\{[(RT/\varepsilon)\ln(p/\phi_L)]^a\} \tag{4.15}$$

with an adjustable energy spread $\in$ and an constant exponent *a* of 1 –3, preferably 2.

As mentioned above, liquid-phase adsorption is different to gas phase adsorption. In the latter one there are distractive adsorption sites and — a defined interface between adsorbed/condensed phase and gas phase. Liquid adsorption always involves replacement of a solvent molecule by the adsorptive, but there is no distinct border between the liquid adsorbate and liquid bulk. Also heat effects are virtually negligible. However, the isotherms used for liquid adsorption are the same as those for the gas phase if the influence of the solvent phase is neglected.

According to the Dubinin – Polanyi theory, a characteristic temperature-independent relation exists between the adsorption potential and the adsorbed volume for each adsorbent – adsorbate system. Such characteristic curves for various adsorptives are shown in Figures 28-30 for molecular sieves, silica gel, and activated carbon adsorbents. Strictly speaking, such temperature-independent characteristic curves can be valid only for nonpolar systems, because only van der Waals forces are independent of temperature. The characteristic curve is thermodynamically inconsistent with Henry's law because the adsorption isotherms for small partial pressures do not end up in a Henry line. However, the Dubinin – Polanyi theory can also be applied to many polar systems with sufficient accuracy.

The Dubinin equation is suitable mainly for organic adsorptives on activated carbon. The exponent *a*=1 often results for wide-pore activated carbons. For this special case, the Dubinin equation can be transformed into the Freundlich relation. The exponent *a*=2 is often valid for narrow-pore activated carbons, while *a*=3 frequently holds for molecular sieves.

The affinity coefficient β characterizes the wetting behavior of an adsorptive on an adsorbent. Thermodynamic considerations result in the affinity coefficient being interpreted as the free enthalpy *G*° of wetting [80]. If *G*° is known, the adsorption isotherms of various adsorptives can be represented in one diagram (see Fig. 31). In this diagram, the binding potential μ_b referred to the free enthalpy *G*°, i.e., the quantity $\mu_b/G°$ is plotted against the degree of pore filling V_i/V_{is} for benzene, cyclohexane, *n*-heptane, and 1,2-dichloroethane on silica gel at 30 °C.

Figure 31. Ratio of binding potential $\mu_b = RT\ln(\varphi)$ to free enthalpy of immersion G^o with pore filling for benzene, cyclohexane, *n*-heptane and 1,2 dichloroethane on silica gel

Capillary condensation results in adsorption – desorption hysteresis. This effect occurs at higher sorptive concentrations and results in an almost vertical slope of the isotherm (e.g., type II isotherm).

In capillary condensation from the gas phase the binding potential μ_b is correlated with the pore radius *r*, the surface tension $\sigma = \sigma_0 \cos\delta$ with contact angle δ, and the molar

volume v_m by using the Gibbs – Thomson equation

$$\mu_b = 2\sigma v_m / r_0. \tag{4.16}$$

For each relative saturation $\varphi_L = p/\Phi_L$, all pores with $r_0 < r_\varphi$ are considered to be filled completely, where

$$r_\varphi = \frac{2\sigma v_m}{RT \ln(1/\varphi_L)}. \tag{4.17}$$

From measured $\varphi_L(\Theta)$ values the pore radius distribution can be evaluated by inserting the values in Equation (4.17). The smaller the pores, the more dramatic is the effect, and it cannot be neglected for pores smaller than 100 nm. During adsorption the pore wall is dry and δ is smaller compared to the wet pore wall in desorption, where δ higher. The difference in vapor pressure Φ_L is then seen in the form of hysteresis, as depicted in Figure 32. Type H1 hysteresis is observed with cylindrical capillaries and zeolites, type H2 mainly with silica gel, type H3 with wide pores having small openings, and H4 with microporous active carbon having mesopores.

The affinity coefficient β_j of adsorptive *j* can be recalculated from the corresponding coefficient of adsorptive *i* with the aid of Equation (4.14 ff) and the Dubinin equation:

$$\beta_i/\beta_j = v_{mi}\sigma_i/(v_{mj}\sigma_j) \tag{4.18}$$

This procedure is successful for the system activated carbon – organic adsorptive [81]; narrow-pore (pore volume 0.45 cm^3/g) and wide-pore (pore volume 0.63 cm^3/g) activated carbon were used in these studies. The reference adsorptive was benzene.

In Figure 33, the specific adsorbed volume V_i in cubic centimeters of fluid per gram of adsorbent is plotted as a function of $[\log(p/\Phi_L)]^a$ (exponent *a*=2 in the Dubinin equation) for the adsorptives phenol, benzene, acetone, and methanol for both measured values and values recalculated according to Equation (4.15). The agreement between values is quite good at high degrees of pore filling (V_i=0.45 cm^3/g) or at very high relative saturation φ_L; it becomes worse as loading decreases. A similar result was found for wide-pore activated carbon.

Table 5 lists measured and calculated affinity coefficients β/β_B for several organic adsorptives, each related to the value β_B of benzene. It shows that adsorption isotherms of other adsorptives can indeed be estimated to a first approximation via the surface tension σ and the molar volume v_m if the isotherm of a reference adsorptive is known. According to Table 5, the affinity coefficient of benzene for the activated carbon used is β_B=18 kJ/mol, but it depends in principle on the type of carbon and especially on its saturation volume. The lower the saturation volume, the higher is the affinity coefficient; for benzene, 15 < β < 25 kJ/mol [82]. This tendency can also be expected from Equations (4.16-4.18). For a given degree of saturation φ_L and for adsorbents with the same structural parameter *C*, from the Dubinin equation

$$\mu_b/\beta = \text{const} \tag{4.19}$$

This means that the affinity coefficient increases with increasing surface tension σ of the adsorptive and decreasing radius r_f of the concave fluid surface in the pore.

Chloroform	0.88	0.86
Acetone	0.72	0.69
Methylene chloride	0.70	0.71
Methanol	0.38	0.36

4.1.2. *Temperature Dependence of the Saturation Loading*

Real adsorption equilibria exhibit a distinct dependence of the available saturation loading on temperature. While this effect is not fully understood yet, it can be explained by thermal expansion of the adsorbed layer reducing its density. Therefore, the saturation loading near the reference state T_0, q_0 is approximated as [78]

$$q_0(T) = q_0(1 - [T - T_0]\alpha_T) \tag{4.20}$$

where α_T is an appropriate adsorbate heat expansion coefficient. At constant loading *q* the fractional coverage Θ in Section Differential Adsorption Enthalpies is taken to be temperature dependent, by inserting $q_0(T)$ instead of q_0.

4.2. Adsorption Enthalpy

4.2.1. *Differential Adsorption Enthalpies*

Even for energetically heterogeneous surfaces the mean adsorption enthalpy H_a is constant, as it is for homogeneous surfaces, if the temperature is high enough to compensate the energetic heterogeneity $\in$ by the thermal fluctuation *RT*. Then all energetic levels are occupied nearly simultaneously. However the spread of the energy levels $H_a \pm \in$ produces distinct selectivites of the various components at each level. The reason for this is the nonlinear response of the selectivity via its Boltzmann factors leading to deviations from the selectivity based only on mean adsorption enthalpies. At low temperatures the adsorption enthalpy shows a distinct coverage dependence for

heterogeneous surfaces which allows the recalculation of the energy level distribution. Formally, the differential isosteric heat of adsorption H_a may be combined as the constant heat of liquefication H_L for subcritical components and the heat of binding H_b to

$$H_a = H_L + H_b \tag{4.21}$$

where each part obeys the related Clausius – Clapeyron equations for chemical equilbria at constant coverage (isosteric conditions)

$$H_x = -R \frac{\partial \ln (p_x/p_o)_{q=\text{const}}}{\partial(1/T)}. \tag{4.22}$$

Here the index x stands for a,L,b and the corresponding pressures p_x are: p_a=adsorptive equilibrium pressure, $p_L = \Phi_L$=liquid saturation pressure, and $p_b = \varphi = p_a / \Phi_L$. The isosteric heat of adsorption can be derived from the experimental slopes of the equilibria as $\ln(p/p_0)$ against T^{-1} at constant adsorptive loading. Examples of mean adsorption and binding enthalpies on molecular sieve 13X are presented in Table 6 for several components.

On heterogeneous surfaces the differential isosteric heat of adsorption is generally coverage-dependent at lower temperatures. For three of our isotherm examples, Langmuir (L; Eq. 4.1), UniLan (UL; Eq. 4.8) and GM; (Eq. 4.9) they are calculated using Equation (4.22) with q_0=const.

$$H_a(\Theta) = \left\{ \begin{array}{c} H_a = \text{const} \\ H_a + \varepsilon - 2\varepsilon\Theta \\ H_a - \varepsilon \ln (\Theta/[1-\Theta]) \end{array} \right\} \begin{array}{c} (L) \\ (UL) \\ (GM) \end{array} \tag{4.23}$$

The GM equation has weak singularities at Θ=0 and Θ=1 which vanish for the integral adsorption enthalpy. Using a temperature-dependent saturation coverage gives an additional configuration enthalpy [83].

Determination of heats is demonstrated by using the system propane–activated carbon [84]. Figure 25 shows the propane loading of activated carbon as a function of the partial pressure at different temperatures. The logarithm of the partial pressure p_i or of the relative saturation is plotted against the reciprocal of absolute temperature [see Figs. 34A and B for isosteres, i.e., lines of equal loading (x_i=const.)]. Such isosteres are straight lines over a somewhat limited temperature range. If the slope of the lines is multiplied by the gas constant R, the heats of adsorption and binding, respectively, are obtained according to Equations (4.22); these heats are shown in Figure 35 as a function of loading.

Figure 34. Partial pressure p_i (A) and relative saturation φ (B) as a function of the reciprocal of absolute temperature 1/T for propane on activated carbon Loading of adsorbent X, kg/kg is given for each line.

Figure 35. Specific heat of adsorption and heat of binding as a function of loading X for propane on activated carbon

a) Specific heat of adsorption Δh; b) Specific heat of binding Δh_B

Table 6. Heats of adsorption ΔH and binding ΔH_B (estimated) of various materials on zeolitic molecular sieve 13X [85]

Adsorptive	Dipole moment, D	ΔH_i, kJ/mol	$\Delta H_{B,i}$, kJ/mol
Argon	0.0	12	5.5
Oxygen	0.0	14	7.2
Krypton	0.0	15	6.0
Nitrogen	0.0	19	13.4
Carbon monoxide	0.1	24	17.9
Carbon dioxide	0.0	46	20.7
Ammonia	1.46	67	43.3
Water	1.8	95	54.3

4.2.2. *Integral Adsorption Enthalpies*

Evaluating heat balances $Q_{s,e}$ due to changes in the adsorptive loading $\Delta q = q_e - q_s$ requires the use of the integral adsorption enthalpy $I(\Theta)$

$$Q_{s,e} = q_0 m_a [I(\Theta_s) - I(\Theta_e)] \tag{4.24}$$

where $Q_{s,e} = q_{s,e}/q_0$ and m_a is the amount of adsorbent. For q_0=const. the integral adsorption enthalpy is

$$I(\Theta') = \int_0^{\Theta'} d\Theta H_a(\Theta) \tag{4.25}$$

and can again be evaluated for the three equilibria (Eq. 4.23; L, UL, and GM)

$$I(\Theta) = \left\{ \begin{array}{c} \Theta H_a \\ \Theta H_a + \varepsilon\Theta(1-\Theta) \\ \Theta H_a - \varepsilon\{\Theta \ln (\Theta) + (1-\Theta) \ln (1-\Theta)\} \end{array} \right\} \begin{array}{c} (\text{L}) \\ (\text{UL}) \\ (\text{GM}). \end{array} \tag{4.26}$$

4.3. Mixture Equilibria

In industrial practice, fluids usually contain more than one adsorbable component. Even for air – adsorptive or general carrier gas – adsorptive mixtures, the adsorption of air or carrier gas at higher pressure must be considered. However, it can be neglected at low total pressure and thus also at low partial pressure of air. Water vapor has a high interaction energy with oxidic adsorbents and is therefore strongly adsorbed by them. Because many gaseous mixtures contain water vapor in addition to the adsorptive to be separated, the adsorption capacity for the latter is often substantially reduced.

As an example, Figure 36 shows the loading of carbon dioxide at 25 °C as a function of its partial pressure at various equilibrium loadings of water. If a 5A molecular sieve (MS) is preloaded with 0.09 g of H_2O per gram of MS, the equilibrium loading of carbon dioxide drops to a fraction of the loading without water vapor. Therefore, low residual water content of the adsorbent during regeneration must be ensured (see Section Removal of Organic Components from Exhaust Air). Figure 37 shows the dew point of the purge gas used for regeneration as a function of the temperature of regeneration with the residual water content of MS 5 A as parameter.

Water vapor also participates as an adsorptive in the adsorption of organic substances on activated carbon. Because at low saturation the energies of interaction of organic substances with activated carbon are much higher than those of water vapor with activated carbon, water vapor does not reduce the capacity for organic substances. This factor is the basis for the ability of active carbon to adsorb organic substances. With increasing relative saturation of water vapor, capillary condensation can finally occur. The capacity of activated carbon for organic components is then substantially reduced, as described in Section Removal of Organic Components from Exhaust Air.

The closer the adsorption isotherms of two materials are at the same temperature, the more competitive adsorption of both components must be considered.

A useful graphic representation of binary adsorption equilibria employs the methanol – water – silica gel system as an example (see [86]). Figure 38 shows the loading n_M of methanol as a function of the partial pressure p_M of methanol for various partial pressures p_W of water at 50 °C. At a given value of p_M, the loading of methanol decreases as the partial pressures p_W of water increases. Figure 39 shows, also at 50 °C, how increasing partial pressures of methanol reduce the loading of water at a given p_W. Such diagrams at first say nothing about the relationship between the concentration of adsorptive in the gas phase and in the sorbate. Therefore, expressing the loading of adsorbent q_{tot} as a function of the mole fraction y_i can be useful. In Figure 40, the loadings of methanol and water are plotted versus the mole fraction y_M of methanol in the gas phase for various active pressures $p_M + p_W$ at 50 °C. The value y_M=1 represents pure methanol vapor, and y_M=0, pure water vapor. For these limiting cases, at 50 °C the methanol loading (y_M=1) is higher than the water loading (y_W=0).

Methanol loading increases with increasing mole fraction y_M of methanol, while water loading decreases. Above 50°C, all curves $q_i=f\,[y_i,(p_i + p_j)]$ would be displaced downward; at lower temperature, displacement would be upward.

Such diagrams permit determination of the partial loading q_i of individual components, as well as the total loading q_{tot}; however, they say nothing about the composition of the sorbate. The mole fraction x_i of component i in the adsorbate can now be determined from the partial loading q_i according to $x_i=q_i/q_{tot}$, where $q_{tot}= \sum q_j$.

From this, equilibrium diagrams $y_i=f(x_i)$ can be calculated. In Figure 41, the mole fraction x_M of methanol in the sorbate is presented as a function of the mole fraction y_M of methanol in the gas phase for different active pressures $p_M + p_W$, again at 50 °C. Such equilibrium curves may exhibit different shapes at other temperatures and at other active pressures.

Mixture equilibria with n components usually are represented as $q_j=q_j(p_1,p_2,p_3, \ldots T)$. In the case of binary mixtures the representations preferably are $x – y$ and q_{tot} diagrams, e.g., $x_1(y_1)$ and $q_{tot}(y_1)$, where $x_1=q_1/q_{tot}$, $y_1=p_1/p$, and $q_{tot}=q_1 + q_2$ is the total loading.

4.3.1. *Homogeneous Surfaces*

The Langmuir equation has an extension for mixtures which is exact under the hypothesis of a perfect homogeneous surface exhibiting an identical saturation loading for all components [87]. Then the fractional coverage for component i in a mixture of n components is

$$\Theta_i = \frac{q_i}{q_0} = \frac{p_i/\phi_i}{1+\sum_{j=1}^{n} p_j/\phi_j}, \tag{4.27}$$

and the total loading is

$$q = q_0 \sum_{j=1}^{n} \Theta_j. \tag{4.28}$$

For an approximation, the saturation loading may be inserted as component- and temperature-dependent, e.g., q_0 is replaced by $q_{0i}(T)$.

4.3.2. *Mixture BET Equation*

The BET equation (Eq. 4.11) can be extended to mixtures by using $\varphi_i=p_i/\,\Phi_{Li}$, $b_i= \Phi_i/\,\Phi_{Li}$,

$$\phi_{Li} = p_0 e^{A_i - H_{ti}/(RT)}, \psi = \Sigma\varphi_j, B = \left(\Sigma b_j \varphi_j\right)/\psi, S_i = b_i/B \tag{4.29}$$

$$\Theta_i = \frac{B\varphi_i}{1-\psi}\frac{1+(S_i-1)(1-\psi)+\psi^N[N+S_i]}{1+(B-1)\psi-B\psi^{N+1}}$$

where $\Theta_i = q_i/q_{0i,mon}$ is related to the monolayer saturation loading $q_{0i,mon}$. For N=1 the equation results in the extended Langmuir equation (4.27).

4.3.3. *Ideal Adsorbed Solution Theory*

The basic n-component equations of the real and ideal adsorbed solution (RAST/IAST) with $y_i = p_i/p$ and $x_i = q_i/\Sigma q_j$ [10] are

$$q_i P = \gamma_i x_i P_j(\pi, T) \tag{4.30}$$

$$q_j = x_j/\Sigma[x_j/Q_j(\pi, T)] \tag{4.31}$$

Summation (j=1 . . .n) and the boundary conditions Σy_i=1 and Σy_i=1 are used to solve Equations (4.31) iteratively. To fit real conditions, activity coefficients $\gamma_i \neq 1$ have been introduced (RAST). For the ideal solution (IAST) approach they are unity (γ_i=1). The key issue of Equations (4.30) and (4.31) are $P_i(\pi,T)$ and $Q_i(\pi,T)$, which are the pure gas equilibrium pressure and loading Q related to the same spreading pressure, i.e., surface energy π for all components.

4.3.3.1. *Spreading Pressure*

The spreading pressure concept uses the Gibbs – Duhem relation for adsorbates

$$S\mathrm{d}T - a\mathrm{d}\pi + N\mathrm{d}\mu = 0 \tag{4.32}$$

which simplifies to the Gibbs isotherm at constant temperature

$$\mathrm{d}\pi = (N/a)\mathrm{d}\mu \tag{4.33}$$

where N is the amount adsorbed, a the surface area, and S the entropy. Equating N/a with $\Theta q_0/\sigma$, where $q = \Theta q_0$ and σ is specific surface area, and the ideal gas chemical potential is equal to the adsorption potential at equilibrium

$$\mu = \mu_0 - RT\ln(p/p_0) \tag{4.34}$$

the spreading pressure is derived as

$$\pi(P, T) = (RTq_0/\sigma)\int_0^P \mathrm{d}p(\Theta(p)/p) \tag{4.35}$$

by using the pure gas fractional coverage $\Theta(p)$. For practical applications it is convenient to work with the reduced spreading pressure π', summarizing all component independent parameters:

$$\pi'(P, T) = \pi\sigma/(RT) = q_0\int_0^P \mathrm{d}p(\Theta(p)/p) \tag{4.36}$$

Examples are displayed in Figure 42. Evaluating the integral of Equation (4.36) for three isotherm relations, Langmuir (L, Eq. 4.1), UniLan (UL, Eq. 4.8), and (GM, Eq. 4.9) gives analytical expressions only for L and GM, while the UniLan equation has to be solved analytically. The analytical solutions are

$$\pi'(P_i, T) = \left\{\begin{matrix} q_{0i}\ln(1+p_i/\phi_i) \\ \left\{q_{0i}/a_i(T)\right\}\ln\left(1+[p_i/\phi_i]^{a_i(T)}\right)\end{matrix}\right\}\begin{matrix}(\mathrm{L})\\(\mathrm{GM})\end{matrix} \tag{4.37}$$

where the exponent $a_i(T)$ is defined in Equation (4.10). The inverse function $P_i(\pi,T)$ to be inserted into the first IAST equation (4.31) is

$$P_i(\pi', T) = \left\{\begin{matrix} \phi_i\left(e^{\pi'/q_{0i}}-1\right) \\ \phi_i\left(e^{\pi' a_i(T)/q_{0i}}-1\right)^{1/a_i(T)}\end{matrix}\right\}\begin{matrix}(\mathrm{L})\\(\mathrm{GM}).\end{matrix} \tag{4.38}$$

Using the isotherm relations we derive $Q_i(\pi,T)$ for insertion into the second IAST equation (4.31) as

$$Q_i(\pi, T) = \left\{\begin{matrix} q_{0i}\left(1-e^{-\pi'/q_{0i}}\right) \\ q_{0i}\left(1-e^{-\pi' a_i(T)/q_{0i}}\right)\end{matrix}\right\}\begin{matrix}(\mathrm{L})\\(\mathrm{GM}).\end{matrix} \tag{4.39}$$

4.3.3.2. *Examples for Binary Mixture Calculations*

4.3.3.2.1. Given Gas-Phase Concentration

Find the componentwise adsorptive loading of a 30/70 % gas mixture of CH_4/N_2 on an activated carbon at T=25 °C and p=20 bar with the IAS model and alternatively with the extended Langmuir equation of Markham and Benton

Pure-Gas Parameters. Isotherm parameters of CH_4 as first component:

$$q_{01} = 1.55\ \mathrm{mol/kg} \quad H_{a1} = 18.3\ \mathrm{kJ/mol} \quad \phi_{01} = 2.02\ \mathrm{bar}$$

related values:

$$H_{a1}/R = 2201\ K \quad \phi_1\left(25^\circ C\right) = \phi_{01}e^{2201(1/273-1/298)} = 4.00\ \mathrm{bar}$$

$$y_1 = 0.3 \quad \varphi_1 = y_1 p/\phi_1 = 1.50$$

Isotherm parameters of N_2 as second component:

$$q_{02} = 4.57\ \mathrm{mol/kg} \quad H_{a2} = 13.1\ \mathrm{kJ/mol} \quad \phi_{02} = 7.37\ \mathrm{bar}$$

related values:

$$H_{a2}/R = 1585\ K \quad \phi_2\left(25^\circ C\right) = \phi_{02}e^{1585(1/273-1/298)} = 12.00\ \mathrm{bar}$$

$y_2 = 0.7 \quad \varphi_2 = y_2 p / \Phi_2 = 1.17$

IAS Calculation. The IAS calculation with $\gamma_1 = \gamma_2 = 1$ and the reduced spreading pressure π' for constant T and σ yields from Equation 4.30 by inserting Equation (4.39) for $P_i(\pi, T)$ from the Langmuir case

$$x_i = y_i p / P_i(\pi, T) = (y_i p / \phi_i) / (e^{\pi'/q_{0i}} - 1) = \varphi_i / (e^{\pi'/q_{0i}} - 1) \tag{4.40}$$

leading to the equation

$$x_1 + x_2 = 1 = 1.50 / (e^{\pi'/5.55} - 1) + 1.17 / (e^{\pi'/4.57} - 1)$$

which is iteratively solved by variation of π (the same π' for both components). The result is

$$\pi' = 6.67 \text{ mol / kg}$$

The spreading pressure is $\pi RT\, \pi' / \sigma = 17$ J/m^2 for a typical specific surface area σ of 10^6 m^2/kg.

Summarizing

$$x_1 = 1.50 / (e^{6.67/5.55} - 1) = 0.645 \quad x_2 = 1.17 / (e^{6.67/4.57} - 1) = 0.355$$

The total mixture loading follows by using $Q_i(\pi, T)$ from Equation 4.39 (L)

$$Q_i(\pi', T) = q_{0i}[1 - e^{-\pi'/q_{01}}]$$

and Equation (4.31) as

$$q_{tot} = 1 / [x_1 / Q_1(\pi', T) + x_2 / Q_2(\pi', T)] \tag{4.41}$$

and evaluated as

$$q_{tot} = 1 / \{0.645 / [5.55(1 - e^{-6.67/5.55})] + 0.355 / [4.57(1 - e^{-6.67/4.57})]\} = 3.74 \text{ mol / kg}$$

where $q_1 = x_1 q_{tot} = 2.41$ mol/kg and $q_2 = x_2 q_{tot} = 1.33$ mol/kg.

The selectivity is $S_{12} = (x_1/y_1)/(x_2/y_2) = (0.645/0.3)/(0.355/0.7) = 4.24$.

Markham – Benton Calculation. With Equation 4.27 and the related φ_i from the above pure-gas calculation

$$q_i = q_{0i} \varphi_i / (1 + \Sigma \varphi_j) \tag{4.42}$$

and inserting

$$q_1 = 5.55[1.50/(1 + 1.50 + 1.17)] = 2.27 \text{ mol / kg}$$

$$q_2 = 4.57[1.17/(1 + 1.50 + 1.17)] = 1.46 \text{ mol / kg}.$$

$$q_{tot} = 3.73 \text{ mol / kg} \quad x_1 = 0.609 \quad x_2 = 0.391 \quad S_{12} = 3.63$$

experimentally q_{tot} was 3.75 mol/kg, x_1 was 0.6, and hence S_{12}=3.5.

4.3.3.2.2. Given Loading

Find the componentwise partial pressures for the example of Section Given Gas-Phase Concentration but with total loading q_{tot} of 3.0 mol/kg and a CH_4 loading of q_1=1.2 mol/kg for the adsorbed CH_4/N_2 mixture on activated carbon at T=25 °C.

IAS Calculation. The calculation steps are now of inverse order compared to a given gas-phase content. Taking the isotherm parameters from the pure-gas calculation of Section Given Gas-Phase Concentration and using the related values

$$x_1 = 0.4 \quad \Theta_1 = x_1 q_{tot} / q_{01} = 0.216$$
$$x_2 = 0.6 \quad \Theta_2 = x_2 q_{tot} / q_{02} = 0.394$$

in the IAS calculation with $\gamma_1 = \gamma_2 = 1$ starting with the second IAS equation we obtain with Equation (4.41)

$$q_{tot} = 1 / \{x_1 / Q_1(\pi', T) + x_2 / Q_2(\pi', T)\}.$$

inserting $x_i = q_i / q_{tot}$ and $\Theta_i = q_i / q_{0i}$ we derive the equation

$$\Theta_1 / (1 - e^{-\pi'/q_{01}}) + \Theta_2 / (1 - e^{-\pi'/q_{02}}) = 1$$

or with Θ_1 = 1.2/5.55 = 0.216 and Θ_2 = 1.8/4.57 = 0.394

$$0.216 / (1 - e^{-\pi'/5.55}) + 0.394 / (1 - e^{-\pi'/4.57}) = 1$$

which is iteratively solved by variation of π'. The result is

$$\pi' = 4.63 \text{ mol / kg}$$

Inserting into Equation (4.30) using Equation (4.39)

$$p_1 = y_1 P = x_1 P_1(\pi', T) = x_1 \phi_1 (e^{\pi'/q_{02}} - 1) = 0.4 \cdot 4.0 (e^{4.63/5.55} - 1) = 2.1 \text{ bar}$$

$$p_2 = y_2 P = x_2 P_2(\pi', T) = x_2 \phi_2 (e^{\pi'/q_{02}} - 1) = 0.6 \cdot 12.0 (e^{4.63/5.57} - 1) = 12.6 \text{ bar}$$

Therefrom y_1=0.143 and p=14.7 bar. The selectivity is

$$S_{12} = (x_1/y_1)/(x_2/y_2) = (0.4/0.143)/(0.6/0.857) = 4.00$$

Markham – Benton Calculation. Equation (4.27) can be rearranged to

$$p_i = \phi_i \Theta_i / (1 - \Sigma \Theta_i) \tag{4.43}$$

where $\Theta_i = q_i / q_{0i}$. Inserting Θ_1=0.216, and Θ_1=0.394 from the above IAS calculation

$$p_1 = 4.0[0.216/(1 - 0.216 - 0.394)] = 2.2 \text{ bar}$$

$$p_2 = 12.0[0.394/(1 - 0.216 - 0.394)] = 12.1 \text{ bar}$$

and the total pressure is 14.3 bar, y_1=0.154 and the selectivity turns out as S_{12}=3.65. The small deviations of the different approaches from each other and the experimental data mainly reflect the (poor) pure-gas approximation as ideal equilibria neglecting all contributions from the heterogeneous surface.

4.3.4. *Statistical Thermodynamics Model*

The statistical thermodynamics (ST) model [88] is suitable for adsorbents with a cage structure (zeolitic molecular sieves). The configuration integrals are approximated by simple expressions that contain the Henry coefficient and the molar volume. The model has been extended to binary adsorption equilibria [89]. The most important assumption made in this model is that the adsorbed molecules are enclosed cages, with practically no exchange of molecules between individual cages. Further, the molecules are assumed to be free to move within the cage; i.e., attractive forces can be neglected. Repulsion of the molecules is taken into account by reducing the cage volume. Because of these assumptions, the model is suitable only for the adsorption of nonpolar molecules of approximately equal size in adsorbents with a cage structure.

Therefore, a simplified statistical thermodynamics model was proposed in 1985, which takes into account both the interactions between molecules and their localization on the adsorbent. The single-component adsorption isotherm can then be described by Equation (4.44) [88, 89].

$$n_i^k = \frac{h_i p_i + (h_i p_i)^2 \; R_{1i} + (h_i p_i)^3 \; \frac{R_{2i}}{2!} + \; \ldots \; + (h_i p_i)^{m_i} \; \frac{R_{mi}}{(m_i - 1)}}{1 + h_i p_i + (h_i p_i)^2 \; \frac{R_{1i}}{2!} + (h_i p_i)^3 \; \frac{R_{2i}}{3!} + \; \ldots \; + (h_i p_i)^{m_i} \; \frac{R_{mi}}{(m_i - 1)!}} \tag{4.44}$$

or

$$n_i^k = \frac{h_1 p_1 + \sum_j \sum_i \frac{(h_1 p_1)^i (h_2 p_2)^j}{i!j!} \left(R_{1s}^i R_{2s}^j \right)^{\frac{1}{i+j}}}{1 + h_1 p_1 + \sum_j \sum_i \frac{(h_1 p_1)^i (h_2 p_2)^j}{i!j!} \left(R_{1s}^i R_{2s}^j \right)^{\frac{1}{i+j}}} \tag{4.45}$$

where $i + j = s$ and $iV_{M1} + jV_{M2} \leq V_K$

The constants R_{1i}, R_{2i}, . . .R_{mi} describe the configuration integrals of statistical thermodynamics and must be determined from single-component adsorption isotherms. Because of this, the number and quality of these constants are of paramount importance. Only two or three constants should be determined, and only after the Henry coefficient h_i has been fitted carefully to reliable measured data, especially at low partial pressure p_i. The two-component adsorption isotherm for component 1 (index 1), for example, then follows from Equation (4.44).

A cage thus contains *s* molecules, i.e., *i* molecules of component 1 and *j* molecules of component 2. The volume occupied by the molecules ($iV_{M1} + jV_{M2}$) must, of course, be smaller than the cage volume V_K. The number n_2^k of molecules of component 2 in the cage is given by an analogous relation.

This simplified statistical thermodynamic model is capable of calculating two-component adsorption isotherms for the following systems from single-component isotherms: *n*-heptane – cyclohexane and ethylene – ethane on molecular sieve 13X, as well as ethylene – propane, carbon dioxide – ethylene, and cyclopropane – ethylene on molecular sieve 5A. This model is probably useful only if the deviation of the adsorbate components from ideal behavior is small. This is often nearly the case when the total loading is less than one molecule per cage. For nonideal behavior and especially for azeotropic behavior (i.e., the equilibrium curve $x=f(y)$ intersects the diagonal line, at this point $x=y$), different molecular volumes and varying interactions of dissimilar molecules must be accounted for by additional coefficients which can be determined only from the equilibrium of the mixture, not from single-component equilibria alone.

KRISHNA showed that configurational entropy can be matched with CBMC (configurational-bias Monte Carlo). In a 50:50 mixture of *n*-hexane (nH) and 3-methyl pentane (3MP) the latter has a maximum loading at 100 Pa (362 K) which decreases at higher pressures virtually to zero. The nH molecules fit nicely in both straight and zig-zag channels, whereas the 3MP molecules are preferentially located at the intersections (cages) between the straight and zig-zag channels in the zeolite. At higher pressure 3MP is then replaced by nH. This corresponds to a sharp increase of sorption selectivity beyond a total loading of four molelcules per unit cell, corresponding to a situation in which all intersections are occupied [90]. Kinetic Monte Carlo and related techniques [33] can also be used to describe diffusion in ordered structures such as zeolites and carbon nanotubes for separation of, e.g., ethane isomers [91].

[Top of Page]

5. Kinetics

The term kinetics generally refers to the rate at which thermodynamic equilibrium is established in a system that is not in equilibrium. In the case of adsorption, the fluid concentration c_i or the partial pressure p_i is greater than the value that is in equilibrium with the loading of the adsorbent. Adsorption continues until the equilibrium loading associated with the fluid concentration is reached.

The reverse process occurs during desorption. As a result of a temperature increase for the adsorbent (regeneration by temperature swing) or a reduction in (partial) pressure (regeneration by pressure swing), the fluid concentration c_i or the partial pressure p_i is smaller than the value in equilibrium with the loading of the adsorbent. Again, desorption continues until equilibrium is established.

The transport of heat and mass in an industrial adsorber takes place in the interstitial bulk phase between the solid particles and is coupled to the balances inside each pellet. When considering mass transfer the adsorptive must overcome the following resistances:

1. Transport from the bulk phase through the boundary layer around the pellet
2. Transport in the fluid and adsorbed phases within the pore system
3. Adsorption

The desorption process occurs in the reverse manner; i.e., it begins with desorption and ends with transport from the concentration boundary layer around the pellet into the fluid volume. In exothermic adsorption, heat is released which is transferred to the adsorbent and the fluid. The adsorbent heats up. In endothermic desorption, heat is required, and the adsorbent cools. Therefore, additional equations for the conservation of energy must be formulated for individual balance volumes. Because of the enormous computational expense involved in solving these equations of conservation, the kinetics are often described only for the isothermal case. The results thus obtained are valid only if the concentration of adsorptive and the heat of adsorption are low or if the system is not very sensitive to temperature.

A similarity exists between fixed-bed adsorbers and heterogenous catalytic reactors. If the reaction rate is faster than the transport rates, then the models are identical; otherwise a chemical reaction adds terms. Thus, much information can be drawn from studies of reactors [92-97]. The same is true for drying, where similar information can be retrieved from the literature, especially in regard to mass transport onto solids [98, 99].

5.1. External/Internal Transport

The transfer of heat and mass between a bulk phase (c_B) and a solid interphase (c_s) takes through a laminar film according to the film theory [100]. For mass transfer this is then

$$n = \beta(c_S - c_B) \tag{5.1}$$

and heat transfer

$$q = \alpha(T_S - T_B) \tag{5.2}$$

However, the dominant mass transfer resistances are usually inside the pellet, whereas the dominant heat transfer resistance is mostly in the film. This is true for liquid- and gas-phase systems, whereby heat effects in liquid adsorption are often negligible.

5.1.1. *Internal Resistances*

Viscous Flow. Within the pellet the transport mechanism of the solute is either in the gas or liquid adsorbed phase. If the pore diameter is considerably (e.g., ten times) larger than the mean free diffusion path, then there is viscous flow. This occurs especially when there is a pressure gradient as in pressure swing adsorption. The mass flow is then determined by the Hagen – Poisseuille law, and the laminar flow in a pore is described by:

$$\dot{v} = -\frac{d_M^2}{32\eta}\frac{\partial P}{\partial z} \tag{5.3}$$

where P is the total pressure, d_M the diameter of the macropore, and η the dynamic viscosity. In a porous system the tortuosity of the pores must be considered as

$$z = \mu_{\mathrm{p,lam}} \cdot r \tag{5.4}$$

The mass flux density for a compound is proportional to the local gas density:

$$\dot{m}_i = \dot{v} \cdot \rho_i \tag{5.5}$$

or

$$\dot{m}_1 = \frac{d_M^2}{32\mu_{\mathrm{p,lam}}\eta}\frac{\partial P}{\partial r}\rho_i \tag{5.6}$$

The influence of the pore size geometry is expressed in the factor $d_M^2/\mu_{\mathrm{p,lam}}$. The smaller the pores, the higher the transport resistance, and larger pores will contribute to a laminar mass flow. An empirical estimate for the tortuosity is given by [99].

$$\mu_{\mathrm{p,lam}} \approx \mu_D^{2.6} \tag{5.7}$$

Diffusional Flow. Besides viscous flow the dominant transport mechanism in the gas phase in smaller pores is free diffusion or Knudsen diffusion. A criterion to distinguish between the two mechanisms is the Knudsen number *Kn*:

$$Kn = \frac{\Lambda}{d} \tag{5.8}$$

where the mean free diffusion path Λ can be derived from the kinetic gas theory:

$$\Lambda = \frac{kT}{\sqrt{2}\pi\sigma^2 P} \tag{5.9}$$

where k is the Boltzmann constant, T the temperature, and σ is the collision diameter. It can be calculated from transport properties or the second virial coefficient and is available from various sources [101].

Knudsen diffusion prevails if $Kn > 10$ (or $d < 0.1\ \Lambda$) where

$$\dot{m} = -\frac{4}{3}\frac{d}{\mu_{\mathrm{p},Kn}}\sqrt{\frac{M_i}{2\pi RT}}\frac{\partial p_i}{\partial r} \tag{5.10}$$

The diffusivity is then given by:

$$D_{Kn} = \frac{4}{3}\frac{d}{\mu_{\mathrm{p,Kn}}}\sqrt{\frac{M_i}{2\pi RT}} \tag{5.11}$$

The empirical tortuosity relation after [99] is:

$$\mu_{\mathrm{p},Kn} = \mu_{\mathrm{p}}^{1.7} \tag{5.12}$$

If $Kn < 0.1$ (or $d > 10\ \Lambda$) then *free diffusion* prevails, as described by Fick's law

$$\dot{m} = -\frac{D_{ij}}{\mu_{\mathrm{D}}}\frac{M_i}{RT}\frac{\partial p_i}{\partial r} \tag{5.13}$$

where D_{ij} is the binary diffusion coefficient, and the tortuosity μ_D must be estimated experimentally or obtained elsewhere [22]. In the slip flow region ($0.1 < Kn < 10$) neither mechanism can be neglected.

Surface Diffusion. As there is a concentration gradient in the pores in the gas phase there is a similar one in the adsorbate on the pore wall. This driving force is referred to as surface diffusion and is low in a monolayer and may be considerable at high coverage. The transport mechanism is considered as a hopping of molecules between adsorption sites [102], which could be also simulated by molecular dynamics simulations [103]. The transport equation is similar to that in the gas phase

$$\dot{m} = -\rho_\theta D_{\mathrm{S}}\frac{\partial X}{\partial r} \tag{5.14}$$

where X is the local sorptive loading, ρ_θ the sorbate density, and D_S the surface diffusivity.

In principle there are two limiting cases [22]:

1. A monomolecular adsorption layer will occur as $D_S \longrightarrow 0$, since the adsorptive has a strong interaction with the active sites.
2. When the capillary is completely filled with condensate then $D_S \longrightarrow \infty$, which means there is a capillary flow without a gradient. The differences in the local capillary pressure are then the reason for liquid flow in an unsaturated porous medium [104-106]. Clearly, in liquid adsorption this phenomenon is more likely than in gas adsorption. However, activated carbon and silica gels will show surface diffusion if the relative humidity is higher than 40 %.

Intracrystalline Diffusion. Intracrystalline diffusion in the micropores, also known as activated slit diffusion [107], can play a limiting role in adsorption and desorption [22, 63]. Here the sorptive diameter is on the order of magnitude of the diameter of the pores, so it is difficult to distinguish from surface diffusion. The transport equation is then analogous to Equation (5.14)

$$\dot{m} = -D_0^0\rho_\theta\frac{\partial X}{\partial r} \tag{5.15}$$

where D_0^0 is the micropore diffusion coefficient. In liquid adsorption, intercrystalline diffusion is lumped together with surface diffusion and not considered separately.

5.1.2. *Linear Driving Force and Other Models*

In chemical catalysis the dusty-gas model is used as a standard to describe diffusion in a porous media. The pore walls or the solid matrix are considered as giant gas molecules ("dust") in an ideal gas mixture. In a formal way the mole fraction of dust can be adapted to account for all diffusional effects from free to Kundsen diffusion [33, 108-110]. In structured geometries like those of zeolites it is nowadays possible to describe surface diffusion and diffusion in narrow pores with statistical mechanic methods such as molecular dynamics or Monte-Carlo simulations [33]. However, in industrial practice, coupling of several mass-transfer resistances with the fixed-bed absorber balance results in a mathematically tedious enterprise. Additionally, in industrial practice a detailed knowledge of the rate-determining steps is not always available, so the linear driving force model (LDF) is often applied. This is why it is generally used in liquid adsorption. All the intraparticle resistances are neglected, and an effective mass transfer resistance in the laminar film is rate-determining

$$\frac{\partial q}{\partial t} = k_{\mathrm{eff}}\left(q_B - q_s\right) \tag{5.16}$$

Here q_S is the average overall amount in the particle and q_B is the equilibrium loading with respect to the bulk concentration c_B. There is an approximation for k_{eff} if the Fourier number $D_{\mathrm{eff}}t/r_{\mathrm{p}}^2 < 0.1$ [111]:

$$k_{\mathrm{eff}} = \frac{15D_{\mathrm{eff}}}{r_{\mathrm{p}}^2} \tag{5.17}$$

However, the validity should be checked prior to use. The diffusion time constant $D_{\mathrm{eff}}t/r_{\mathrm{p}}^2$ is in the order of 10^{-1} s^{-1} for activated carbon and 10^{-3} s^{-1} for zeolite crystals. This makes the application of LDF in the initial periods of uptake invalid, especially for zeolite crystals [63]. Results obtained with the Glueckauf formulation are often in good agreement with the more accurate macropore diffusion model while requiring less calculation time [112].

An alternative approach used with the desorption of water [113] considered the desorptive transfer process as a first-order kinetics rate [82]:

$$\frac{\mathrm{d}q}{\mathrm{d}t} = k_{\mathrm{des}} \cdot q_{\mathrm{B}} \tag{5.18}$$

With the temperature dependency using the isosteric activation energy E_a

$$k_{\mathrm{des}} = k^0 e^{-\frac{E_a}{RT}} \tag{5.19}$$

and a frequency factor [114]

$$\ln k^0 = a + b e^{-cq_{\mathrm{B}}^2} \tag{5.20}$$

where *a*, *b*, *c* are adjustable parameters.

The kinetics of nonisothermal ad- and desorption are more complex and discussed in detail in [22], and multicomponent adsorption has so far not been well investigated. According to [83] one can assume that the molecule – molecule interactions are ten times smaller than molecule – wall interactions. However, multidiffusional effects play a vital role in pressure-swing adsorption. In this regard, diffusion and friction in multicomponent mixtures in porous systems using the Maxwell – Stefan diffusion law has been discussed by several authors [115, 116].

[Top of Page]

6. Adsorber Dynamics

Mass and heat transport in an adsorber bed result in a breakthrough curve which can be simulated appropriately. Depending on the scope of the results the models are then more or less sophisticated.

The simplest approach is an *equilibrium model* considering a convective gas phase in equilibrium with the stationary phase. This is a good approach for a rough estimation of the bed behavior. To account for backmixing, i.e., the deviation from plug flow, a tank-in-series model can be used. This is equivalent to the dispersion or back-flow models, in which one parameter accounts for all flow nonidealities [94, 117].

Nonequilibrium models additionally consider the mass (heat) transfer from the bulk gas phase to the adsorbent. With more sophisticated models a balance inside the particle is made with consideration of the kinetics behavior (see Chap. Kinetics). However, both gas and liquid adsorption models are usually simplified, and the LDF model is considered appropriate and efficient to account for the major effects.

6.1. Modeling the Isothermal Fixed-Bed Adsorber

Figure 43 shows a fixed-bed adsorber of cross-sectional area *A* with a volume flow $\dot{V}$ passing through it. The volume flow density $\dot{v}$ is then $\dot{v} = \dot{V}/A$. The adsorber contains monodisperse particles of adsorbent with radius R_a. Let the porosity of the packing be Ψ, which represents the ratio of void volume to packing volume. If the adsorbent exhibits a bimodally dispersed pore structure with macropores and cage-type micropores, as is the case with zeolitic molecular sieves, the micropore system is then located within the zeolite crystals, which are assumed to be monodisperse and have the radius r_a.

Figure 43. Balance volumes in molecular sieve 5A fixed bed

a) Pellet; b) Adsorber; c) Zeolite crystals; d) Macropore; e) Outer boundary layer; f) Micropore

Material balances in the fixed-bed adsorber which correspond to these assumptions can then be formulated for three balance volumes:

1. Balance in the adsorber with differential bed height d*z* (fixed-bed absorber):

$$\begin{gathered}\frac{\partial c_i}{\partial t} + \frac{1-\psi}{\psi}\rho_{\mathrm{p}}\frac{\partial \overline{X}_{m,i}}{\partial t} = \frac{\dot{v}}{\psi}\frac{\partial c_i}{\partial z} + D_{\mathrm{ax}}\frac{\partial^2 c_i}{\partial z^2} \\ c_i(z, t=0) = 0; \quad c_i(z, t=0) = c_{0,i}; \quad \frac{\partial c_i}{\partial z}(z = Z, t) = 0; \\ \underbrace{c_i(z=0, t) = c_{0,i,\mathrm{ad}} + \frac{D_{\mathrm{ax}}\psi}{\dot{v}}\frac{\partial c_i}{\partial z};}_{\text{Adsorption}} \quad \underbrace{c_i(z=0, t) = c_{0,i,\mathrm{des}} + \frac{D_{\mathrm{ax}}\psi}{\dot{v}}\frac{\partial c_i}{\partial z}}_{\text{Desorption}}\end{gathered} \tag{6.1}$$

2. Balance in the macropores of the particle (radius R_a):

$$\frac{\partial c_{M,i}}{\partial t} + \frac{\rho_{\mathrm{p}}}{\varepsilon_{\mathrm{p}}}\frac{\partial \overline{X}_{m,i}}{\partial t} = \underbrace{\frac{1}{R^2}\frac{\partial}{\partial R}\left(R^2\frac{D_{M,i}}{\mu_{\mathrm{p}}}\frac{\partial c_i}{\partial R}\right)}_{\text{Fluid phase}} + \underbrace{\frac{1}{R^2}\frac{\partial}{\partial R}\left(R^2\frac{\rho_{\mathrm{p}}}{\varepsilon_{\mathrm{p}}}D_{s,i}\frac{\partial \overline{X}_{m,i}}{\partial R}\right)}_{\text{Sorbate phase}} \tag{6.2}$$

Transport only in fluid phase:

$$\begin{gathered}\underbrace{c_{M,i}(R, t=0) = 0;}_{\text{Adsorption}} \quad \underbrace{c_{M,i}(R, t=0) = c_{0,i};}_{\text{Desorption}} \quad \frac{\partial c_{M,i}}{\partial R}(R=0, t) = 0 \\ \beta_i(c_i - c_{M,i})\Big|_{R=R_a} = \frac{\varepsilon_{\mathrm{p}}}{\mu_{\mathrm{p}}}D_{M,i}\frac{\partial c_{M,i}}{\partial R}\Big|_{R=R_a}\end{gathered} \tag{6.3}$$

3. Balance in the zeolite cages of the crystal (radius r_a):

$$\begin{gathered}\frac{\partial X_{m,i}}{\partial t} = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 D_{m,i}\frac{\partial X_{m,i}}{\partial r}\right) \\ \underbrace{X_{m,i}(r, t=0) = 0;}_{\text{Adsorption}} \quad \underbrace{X_{m,i}(r, t=0) = X_i^*(c_{0,i});}_{\text{Desorption}} \quad \frac{\partial X_{m,i}}{\partial r}(r=0, t) = 0; \\ X_{m,i}(r = r_a, t)\,|_R = X_i^*(c_{m,i}, t)\,|_R\end{gathered} \tag{6.4}$$

In principle, the adsorption and desorption steps can also affect the rate of sorption. This can be described analogously to first-order reactions:

$$\text{Adsorption:} \quad \frac{\mathrm{d}c}{\mathrm{d}t} = k_{\mathrm{ad}}c\left(n^\infty - n\right) \tag{6.5}$$

$$\text{Desorption:} \quad \frac{\mathrm{d}n}{\mathrm{d}t} = k_{\mathrm{des}}n = k_{\mathrm{des}}^0 \exp\left(-\frac{\Delta H}{RT}\right)n \tag{6.6}$$

Numerous investigations have shown that in the physical sorption of small molecules, the time required for the adsorption step can be neglected. The same almost always holds true for the desorption step, too. This means that fluid and adsorbate phase are in mutual equilibrium.

The initial and boundary conditions for simple cases are shown below the balance equations. The cases include a bed completely unloaded at the beginning of adsorption, as well as a bed completely loaded uniformly at the beginning of desorption by purging, in which the loading $X_{0,i}^*$ is in equilibrium with the concentration of adsorptive $c_{0,i}$.

Balances must be formulated for each component in multicomponent adsorption and can be applied to both adsorption and desorption. When steam regeneration is applied then additional drying and cooling slips have to be considered, too [118]. The equations contain the changes with time $\partial c/\partial t$ in the concentration of adsorptive and $\partial X/\partial t$ in the loading of adsorbent, as well as various coefficients which are explained next.

6.2. Modeling the Adiabatic Fixed-Bed Adsorber

In principle, fixed beds for adsorption and desorption can be operated *isothermally* (low concentration of adsorptive or low heat of adsorption), *nonisothermally* (removal or supply of heat), or *adiabatically*. In larger diameter industrial adsorbers without internal cooling, the surface-to-volume ratio is so small that heat losses through the outside jacket are small. In such cases, the apparatus is operated approximately adiabatically. Formulas for the *energy balance* of the adsorbent and of the gas for a differential bed height d*z* during adiabatic operation follow.

Adsorbent:

$$\left(1-\psi\right)\rho_s c_s \frac{\partial T_s}{\partial t} = \bar{\alpha} a_{Sch}\left(T_G - T_s\right) + \left(1-\psi\right)\lambda_s \frac{\partial^2 T_s}{\partial z^2} + \left(1-\psi\right)\rho_s \Delta h \frac{\partial X}{\partial t} \tag{6.7}$$

Gas:

$$\psi \rho_s c_G \frac{\partial T_G}{\partial t} = \bar{\alpha} a_{Sch}\left(T_s - T_G\right) \dot{v} \rho_G c_G \frac{\partial T_G}{\partial z} + \psi \lambda_G \frac{\partial^2 T_G}{\partial z^2} \tag{6.8}$$

$$\text{If } Bi = \frac{\alpha d_p}{6\lambda_s} < 1 \tag{6.9}$$

the temperature gradient within the adsorbent particle is small. Then, $\bar{\alpha} = \alpha$ [119], where the heat-transfer coefficient of the particle can be calculated as follows:

$$Nu = \frac{\alpha d}{\lambda_s} = \left[1 + 1.15\left(1-\psi\right)\right] Nu_b \tag{6.10}$$

$$Nu_b = 2 + \sqrt{Nu_{lam}^2 + Nu_{turb}^2} \tag{6.11}$$

$$Nu_{lam} = 0.664\sqrt{Re_\psi} Pr^{1/3} \tag{6.12}$$

$$Nu_{turb} = \frac{0.037 Re_\psi^{0.8} Pr}{1 + 2.44 Re_\psi^{-0.1}\left(Pr^{2/3} - 1\right)} \tag{6.13}$$

To calculate the temperature and concentration profiles, as well as the breakthrough curve, the equations for the conservation of mass (Eqs. 6.1-6.4) and energy (Eqs. 6.7-6.9, 6.10-6.13) must be solved simultaneously. Not many results are available, but qualitative statements are possible in principle. The heat released during adsorption at low temperature is transported through the fixed bed mainly by *conduction* and *convection*. The temperature front thus created migrates through the bed in the direction of flow and is coupled to the concentration front via the temperature-dependent equilibrium and the likewise temperature-dependent kinetics of sorption. Figure 44 shows the situation in which a temperature front is getting rapidly ahead, while Figure 45 applies to a combined front in which concentration and temperature increase simultaneously at the end of the bed. In both figures, the profiles of gas concentration and temperature in the bed are plotted on the left; the breakthrough curves (i.e., the profiles of concentration and temperature at the end of the adsorber) are plotted as a function of time on the right.

Figure 44. Schematic representation of temperature and concentration curves during adsorption in which the temperature front moves rapidly ahead of the concentration front

—— Concentration; – – –Temperature; – · – · – Width of transfer zones.

Figure 45. Schematic representation of temperature and concentration curves during adsorption—combined wave fronts

—— Concentration; – – – Temperature.

According to [120], the temperature front moves rapidly ahead of the concentration front in the case of a linear adsorption isotherm if the condition

$$\frac{c_s}{c_p} < \frac{\Delta X}{\Delta Y} \tag{6.14}$$

is met. If, on the other hand,

$$\frac{c_s}{c_p} \geq \frac{\Delta X}{\Delta Y} \tag{6.15}$$

a combined wave front exists, i.e., concentration and temperature break through at the same time. Because the ratio of the specific heats of gas and adsorbent is approximately one in the case of oxidic adsorbents and with air as the carrier gas, the slope $\Delta X/\Delta Y$ of the adsorption isotherms will be the key to which case actually occurs. If the temperature front moves ahead, the maximum temperature increase $\Delta\theta_{max}$ and hence the plateau temperature θ_{pl} are obtained from a heat and mass balance over the migrating mass-transfer zone:

$$\Delta\theta_{max} = \theta_{pl} - \theta_0 = \frac{\Delta X \Delta h / c_p}{\left(\Delta X/\Delta Y\right) - \left(c_s/c_p\right)} \tag{6.16}$$

The temperature effects are particularly strong with a large difference in loading ΔX of an adsorptive having a high average heat of adsorption Δh and with a low specific heat capacity c_p of the gas. Temperature increases during adsorption and temperature decreases during desorption can be considerable. Figure 46 shows both the concentration ratio c/c_0 and the temperature difference $\Delta\theta = \theta - \theta_0$ versus time for the adsorption of CO_2 on MS 5A. At a feed concentration of 1 vol % CO_2, the temperature moves ahead of the concentration front (curve a); at higher values, a combined front exists. However, the maximum temperature increase is determined not by the kinetics of adsorption but rather by the course of the temperature increase in the mass transfer zone. While any higher temperatures that occur here produce a minor increase in the diffusion coefficients, they nevertheless lead to lower rates of adsorption, because at a given concentration of adsorptive, the adsorbent cannot be loaded as much. For this reason, the type of isotherm field is important.

Figure 46. Adsorption System: CO_2–molecular sieve 5A; c/c_0; $\Delta\theta = f(t)$; θ_0=25°C; v=0.2 m/s; d=2.0 mm; D=100 mm; Z=1.0 m

a) c_0=1.0 vol%; b) c_0=3.0 vol%; c) c_0=10.0 vol%

During *desorption by purging*, the temperature drop increases as the loading of the fixed bed increases due to the preceding adsorption; this is shown in Figure 47. Initially, a combined mass- and heat-transfer zone occurs with a steep drop in concentration and simultaneous cooling of the fixed bed. This is followed by an equilibrium or *plateau*

zone in which the temperature level is so low that desorption stops. Only then does the bed warm up again; the adsorbent is desorbed further, now in a combined wave front. In desorption by purging, a considerable amount of purge gas is necessary in the case of an equilibrium that favors adsorption. In such a case, thermal desorption with a heated gas is recommended. Thereby, the plateau temperature will be slightly higher than the initial temperature and will remain constant until the adsorbent is completely desorbed. Then a steep temperature increase follows. As an example, Figure 48 illustrates the thermal desorption of the system CO_2 – MS 5A at a temperature of 200 °C for the regenerating gas. The concentration of carbon dioxide and the temperature at the end of the bed are plotted for z=0.5 m and z=1 m. Only when the concentration drops does the temperature increase steeply. This behavior shows clearly that equilibrium zones occur in the fixed bed when large deviations from isothermal conditions arise. The adsorption or desorption process can then become heat-transport-limited; i.e., it depends only on the supply and removal of heat, respectively.

6.2.1. *Loading and Breakthrough Curves*

Many literature references verify that Equations (6.1-6.4) describe the rates of both adsorption and desorption on single pellets as well as the breakthrough curves of single- and multicomponent mixtures in isothermally operated fixed beds.

As an example of processes occurring in single pellets during adsorption, as well as during desorption by purging, Figure 49 shows the *change in loading* $\Delta X/\Delta X_{max}$ of carbon dioxide as a function of time for pellets of zeolitic molecular sieve MS 5A with radii R_a of 1.34 and 2.54 mm [119]. The curves apply to pressure jumps from 0 to 3 vol % (adsorption) and from 3 to 0 vol % (desorption). The rate of sorption dX/dt increases as the particle radius decreases. Adsorption is faster than desorption because the adsorption isotherms are strongly curved in a sense that favors the adsorption process. In the calculations, only macropore diffusion in the fluid phase is taken into account. If breakthrough curves for isothermal fixed beds are calculated according to Equations (6.1-6.4), in some cases, transport in the sorbate phase of macropores in planar adsorbents or micropore diffusion in zeolites with cage structure can be neglected.

Figure 50 shows breakthrough curves for a gaseous methanol – water mixture adsorbed at 50 °C on silica gel from nitrogen as carrier gas [86]. An evident hump occurs for the more weakly adsorbed component (water); it leaves the fixed-bed adsorber with a higher concentration than the feed concentration; this roll-over becomes more pronounced, the closer together the adsorption isotherms of the two pure components are. In calculating this curve, only macropore diffusion in the fluid phase is considered in addition to the balance of the fixed-bed adsorber. By contrast, during adsorption of mainly organic materials from the gas [121, 122] and fluid phases [123-125], diffusion in the sorbate phase can contribute substantially to transport in the macropores.

For zeolitic molecular sieves, micropore diffusion in the crystals must sometimes be taken into account during modeling. As an example, Figure 51 shows the relative effluent concentrations of an ethylene – carbon dioxide mixture as a function of adsorption and desorption time at 40 °C [126]. Because the molecular diameters (C_2H_4: 0.43 nm, CO_2: 0.28 nm) are only somewhat smaller than the cage opening (MS 5A: 0.43 nm), and the particle radius (R_a=0.5 mm) is relatively small compared to the radius of the crystal (r_a=0.5 µm), micropore diffusion offers considerably more resistance to transport than macropore diffusion.

6.2.2. *Simplified Models*

Simplified models to describe the dynamic behavior of an adsorber are illustrated by a system with only a single adsorbable component.

Micropore diffusion is important only if

$$\frac{R_a^2 \mu_p D_m}{r_a^2 D_M}\left(\frac{\rho_p X}{\varepsilon_p c}\right) < 10 \qquad (6.17)$$ [126]

. This means that micropore diffusion can be neglected above all when the radius R_a of the particle of adsorbent is large and the radius r_a of the zeolite crystals is small. By using local equilibrium

$$\frac{\partial X}{\partial t} = \frac{\partial X}{\partial c}\frac{\partial c}{\partial t} \qquad (6.18)$$

the law of conservation of mass (Eqs. 6.2 and 6.3) can be simplified for $D_{S,i}$=0 as follows:

$$\frac{\partial c_M}{\partial t} = \underbrace{\frac{D_M/\mu_p}{1+\frac{\rho_p \partial X_M}{\varepsilon_p \partial c_M}}}_{D_{eff}}\left(\frac{2}{R}\frac{\partial c_M}{\partial R} + \frac{\partial^2 c_M}{\partial R^2}\right) \qquad (6.19)$$

This equation defines an “effective” pseudomacropore diffusion coefficient D_{eff} which, however, now contains the slope $\partial X/\partial c$ of the adsorption isotherms. The definition of the

effective diffusion coefficient does not have a strictly physical meaning; it is, however, very convenient for practical calculations because the literature gives solutions for nonstationary diffusion in spheres under various boundary and initial conditions. Nevertheless, the effective diffusion coefficient is independent of loading only if the adsorption isotherms are linear. For this case, ROSEN provides the following solution to the system of equations (isothermal, external mass transfer, and macropore diffusion in the fluid phase, linear isotherms) for the breakthrough curve of the fixed bed [127]:

$$\frac{c(t,z)}{c_\alpha} = \frac{1}{2}\left\{1 + \mathrm{erf}\left[\frac{\frac{\dot{v}(t - z(\psi/\dot{v}))}{Kz} - 1}{2\sqrt{\frac{1+5D_{\mathrm{eff}}(K/(R_a\beta))}{15D_{\mathrm{eff}}Kz\left(R_a^2\dot{v}\right)}}}\right]\right\} \tag{6.20}$$

where $K = \Pi_p\,(dX/dc)/\epsilon_p$ and z is the axial distance in the fixed bed.

Several breakthrough curves calculated in this way are shown in Figure 52. The desired steep slope of the breakthrough curves is obtained if

1. The mass-transfer coefficient is so large that mass transport through the outer concentration boundary layer is nonlimiting
2. The effective diffusion coefficient is large, and hence the coefficients of free and Knudsen diffusion are large, and the tortuosity factors μ_p are small (curve c)
3. The radius of the adsorbent pellet is small (curve e)
4. The volume flow density of the fluid is low and its concentration is high
5. The slope $\partial X/\partial c$ and K for the adsorption isotherms are large

In some cases, external mass transfer can be neglected in comparison to macropore diffusion. This is generally the case when the Biot number is much greater than 1. This occurs frequently in gas-phase adsorption. In that case, the term

$$Bi = \frac{R_a\beta}{3\varepsilon_p D_M/\mu_p} \tag{6.21}$$

$D_{\mathrm{eff}}K/(R_a\beta)$ can be neglected in the Rosen equation.

Instead of nonstationary pore diffusion according to Equations 6.2 and 6.3, the kinetic formulation of GLUECKAUF [111] is often used (see Eqs. 5.16 and 5.17).

If the adsorption isotherms are not linear, the system of equations for the conservation laws of the fixed bed and the macropores must be solved numerically. In so doing, the rates of adsorption and desorption are different. This is due to the curvature of the isotherms.

The example of adsorption on a single pellet illustrates this (see Fig. 53). If the isotherms are curved upward (Fig. 53, top), the equilibrium is favorable for adsorption but unfavorable for desorption. The diagrams at the bottom illustrate an isotherm which is favorable for desorption but not for adsorption. The diagrams on the right show qualitatively the loading profiles versus particle radius that result from calculations based on the macropore diffusion model. Large changes in partial pressure, and hence in the loading of a relatively thin spherical shell of the adsorbent pellet, occur both in adsorption with an isotherm favorable to it (upper left) and in desorption with its favorable isotherm (lower right). In these cases, the maximum difference in partial pressures in the pellet—the driving difference in concentration—is available over a longer period of time. The profiles in the upper right (desorption with an isotherm unfavorable to desorption) and in the lower left (adsorption with an isotherm unfavorable to adsorption) exhibit no steep profiles for partial pressure. This means that over longer periods of time, only a partial pressure difference $\Delta p_i < \Delta p_{i,\max}$ is effective in pore diffusion. With highly curved isotherms, the rates of adsorption and desorption therefore differ substantially. For practical purposes, two cases are distinguished:

1. The isotherm is curved upward; hence, it is favorable for adsorption and unfavorable for desorption. In this case, the rate of adsorption is greater than the rate of desorption.
2. The isotherm is curved downward; hence, it is favorable for desorption but unfavorable for adsorption. In this case, the rate of desorption is greater than the rate of adsorption.

The difference in rates of adsorption and desorption increases with the deviation of the isotherms from linearity. This shows clearly that in processes of adsorptive separation (adsorption of one component with subsequent desorption), the useful shape of the isotherms represents a compromise between two divergent requirements.

Figure 52. Breakthrough curves calculated according to the Rosen equation

Standard case: K_{st}=2540; v_{st}=0.12 m/s; D_{eff}=1.9×10^{-10} m^2/s; $R_{a,s}$=4×10^{-3} m; z=1.5 m; Ψ=0.4

6.2.3. *Coefficients*

The balance equations contain the axial dispersion coefficient D_{ax} of the fixed bed, the mass-transfer coefficient β between fluid and adsorbent particle, the diffusion coefficient D_M in the macropores, and the diffusion coefficient D_m in the zeolite cages.

Axial Dispersion Coefficient. In a fixed-bed adsorber, plug flow is desirable. Deviation from this flow is described by the axial dispersion coefficient D_{ax} or a dimensionless number K of the fixed bed

$$K = \frac{\dot{v}Z}{\psi D_{\mathrm{ax}}} \tag{6.22}$$

This dimensionless number is a function of D_{ax}, the volume flow density $\dot{v}$, the porosity Ψ, and the bed length Z. Two limiting cases can be distinguished.

1. $$\text{Pure plug flow}: \quad \frac{\dot{v}Z}{\psi D_{\mathrm{ax}}} \to \infty \tag{6.23}$$

2. $$\text{Complete mixing}: \quad \frac{\dot{v}Z}{\psi D_{\mathrm{ax}}} \to 0 \tag{6.24}$$

The axial dispersion coefficient is a function of the dimensionless Péclet number Pe

$$D_{\mathrm{ax}} = \frac{\dot{v}d}{\psi Pe} \tag{6.25}$$

where $d=2R_a$ is the particle diameter. The Péclet number depends on the product of the Reynolds number of the particle and the Schmidt number of the fluid:

$$Re\,Sc = \frac{\dot{v}d}{D_{\mathrm{AB}}} \tag{6.26}$$

where D_{AB} is the diffusion coefficient of the fluid. This relationship can be read from Figure 54 [128]. For small characteristic numbers (K < 100), which occur in vacuum and

liquid-phase adsorption, axial dispersion can lead to an earlier breakthrough of the adsorptive compared with plug flow and hence to a reduced usable capacity. For $K > 100$ and $D_{ax} \longrightarrow 0$, the corresponding term in the adsorber balance equation (Eq. 6.1) can be neglected. This is sometimes the case in gas-phase adsorption.

Figure 54. Péclet number *Pe* as a function of *Re·Sc*

Range of validity: 0.008 < *Re* < 400; 0.28 < *Sc* < 2.2

Mass-Transfer Coefficient. The mass-transfer coefficient β between fluid and adsorbent particle surface depends on the Reynolds number of the particle and the Schmidt number $Sc = \nu/D_{AB}$ of the fluid, where ν is the kinematic viscosity. The mass-transfer coefficient can be determined with the aid of Equations 6.27-6.30.

$$Sh_{fb} = \frac{2R_a\beta}{D_{AB}} = \left[1 + 1.5\left(1 - \psi\right)\right] Sh_b \tag{6.27}$$

$$Sh_b = 2 + \sqrt{Sh_{lam}^2 + Sh_{turb}^2} \tag{6.28}$$

$$Sh_{lam} = 0.664\sqrt{Re_\psi}\,Sc^{1/3} \tag{6.29}$$

$$Sh_{turb} = \frac{0.037\,Re_\psi^{0.8}\,Sc}{1 + 2.44\,Re_\psi^{-0.1}\left(Sc^{2/3} - 1\right)} \tag{6.30}$$

The Sherwood number Sh_{fb} in a fixed or moving bed depends on the Sherwood number Sh_b (see Eq. 6.28) of individual beads, which in turn is a function of the Schmidt and Reynolds numbers of the fluid (Eqs. 6.29 and 6.30). Here, the fluid passes the adsorbent particle with an effective velocity $\dot{v}/\psi$. In liquid-phase adsorption, the mass-transfer coefficient can be calculated from similar relations [129].

Macropore Diffusion Coefficient and Tortuosity Factor.
Macropore Diffusion Coefficient. In the macropores, material can be transported by convection and diffusion in the fluid and in the sorbate phases. If a drop of total pressure occurs in gas-phase adsorption, flow will result. Depending on the Knudsen number *Kn* (ratio of the mean free path of molecules to the pore diameter), this may be laminar flow ($Kn < 0.01$), slip flow ($0.01 < Kn < 1$), or molecular or Knudsen flow ($Kn > 1$). If the influence of rapid deflation or pressurization in the adsorber is neglected, and only slow adsorption or desorption processes are considered, mass transport contributions from viscous flow in the pores can often be neglected. Mass is then transported in the fluid phase on the basis of *free diffusion* with diffusion coefficient D_{AB}, as well as *Knudsen diffusion* with diffusion coefficient D_{Kn}. In planar adsorbents, *transport* in the sorbate phase (*surface diffusion*), with diffusion coefficient D_S, may also contribute to the overall mass-transfer rate. If the adsorbent is loaded to only half the monomolecular coverage, transport in the sorbate phase can be neglected because the molecules are almost immobile due to the high energy of binding. Mass is then transported only by free and Knudsen diffusion in the macropores. The coefficients for free diffusion in a gaseous or fluid phase D_{AB} and for Knudsen diffusion D_{Kn} can be calculated from Equations 6.31-6.34. The macropore diffusion coefficient D_M can be determined from them by superposition of the coefficients D_{AB} and D_{Kn} [119, 130]. At high total pressures, $D_M \approx D_{AB}$; in a vacuum, $D_M \approx D_{Kn}$.

Free diffusion:

$$D_{AB} = \frac{2}{3}\sqrt{\left(\frac{k}{\pi}\right)^3}\sqrt{\frac{1}{2m_A} + \frac{1}{2m_B}}\,\frac{\sqrt{T^3}}{p[(d_A + d_B)/2]^2} \quad \text{(Gases)} \tag{6.31}$$

$$D_{AB} = 7.4 \cdot 10^{-12}\frac{\sqrt{\psi_B M_B T}}{\eta(V_A)^{0.6}}\left[\frac{m^2}{s}\right] \quad \text{(Liquids)} \tag{6.32}$$

(M_B in kg/kmol, T in K, V_A in cm^3/mol, η in mPa·s)

Knudsen diffusion:

$$D_{Kn} = \frac{4}{3}\sqrt{\frac{RT}{2\pi}}\,d_M \tag{6.33}$$

Superposition of free gas diffusion and Knudsen diffusion:

$$D_M = \frac{1}{\frac{1-(1+(\dot{n}_B/\dot{n}_A))y_A}{D_{AB}} + \frac{1}{D_{Kn}}} = \frac{1}{\frac{1}{D_{AB}} + \frac{1}{D_{Kn}}} \tag{6.34}$$

(for equimolar counterdiffusion)

Tortuosity Factor. Because macropores are not straight cylinders, but rather tortuous with changing and partly slitlike cross sections, a tortuosity or detour factor μ_p, also called the diffusion resistance factor, must be introduced. On the basis of this definition, the factor should depend only on the structural characteristics of the adsorbent, not on operating conditions such as pressure, temperature, type and concentration of adsorptive, or kind of operation (adsorption or desorption). Such is, however, not the case for many values given in the literature. Often, the quantity μ_p contains either the porosity ϵ_p of the adsorbent particle or the reduction of total diffusion by Knudsen diffusion [131]. In other cases, the coefficient of Knudsen diffusion is calculated for a cumulative undersize passage of the macroporosity of 0.5 [$\epsilon(r_p)/\epsilon_{macro}=0.5$], which may not weight correctly the contributions of pores of various sizes to Knudsen diffusion [119, 126], [132]. Because tortuosity factors are almost always curve-fitting factors resulting from a comparison of measured and calculated breakthrough curves, they are defined by the corresponding calculation model and cannot be applied to other models. Tortuosity factors that do not contain any effects of Knudsen or micropore diffusion (e.g., determined during the adsorption of small molecules in wide micropores at higher pressures) and are corrected for the porosity of the adsorbent should be between 3 and 6.

Diffusion coefficients D_S in the sorbate phase can be determined experimentally only by recording loading curves for a single pellet. This loading curve should be described as accurately as possible by means of the macropore diffusion model. The diffusion coefficient D_S in the sorbate phase is then a curve-fitting parameter. Coefficients determined in this way are often in the range 10^{-7} $m^2/s < D_S < 10^{-12}$ m^2/s [133] and are strongly dependent on temperature because diffusion in the sorbate phase is an activated process.

Micropore Diffusion Coefficient. The micropore or zeolitic diffusion coefficient D_m depends on the coefficient D_0^0, on temperature, and on loading:

$$D_m = D_0^0 \exp\left(-\frac{E_a}{RT}\right)\frac{\partial \ln c}{\partial \ln \overline{X}} = D_0^0 \exp\left(-\frac{E_a}{RT}\right)\frac{\overline{X}\,\partial c}{c\,\partial \overline{X}} \tag{6.35}$$

where $\overline{X}$ is the mean mass loading of adsorbent. The factor D_0^0 and the activation energy E_a are functions of micropore geometry, as well as shape, size, and polarizability of the adsorptive molecules. The larger the critical diameter of the molecules compared to the micropore diameter, the smaller is D_0^0. The activation energy E_a is often between 10 and 40 kJ/mol and increases with molecular diameter [133]. Micropore or zeolitic diffusion coefficients cannot be precalculated; they must be determined experimentally. They are frequently in the range 10^{-16} $m^2/s < D_m < 10^{-11}$ m^2/s and depend, among other things, on the type of adsorptive and zeolite.

[Top of Page]

7. Regeneration of Adsorbents

Loaded adsorbents can be regenerated by temperature or pressure swing processes and by displacement. In some cases, the adsorptive can be extracted from the adsorbent. If the pores of an adsorbent become plugged, reactivation is necessary.

Regeneration is favored at low pressures, high temperatures, and large differences in concentration, which results in pressure swing adsorption (PSA), temperature swing adsorption (TSA), and composition swing adsorption (CSA). Sometimes several effects are used simultaneously, as in steam regeneration, where steam acts as displacer and increases the temperature. In vacuum swing adsorption (VSA) desorption is carried out below atmospheric pressure.

Figure 55 shows how the loading of adsorbent is reduced by an increase in temperature (*temperature swing*, TSA) or by a (partial) pressure reduction (*pressure swing*, PSA). The more the adsorption isotherms favor adsorption, the higher are the heats of adsorption and binding, and the greater is the use of thermal regeneration. Desorption by pressure swing is often economical if the heat of adsorption is less than about 30 kJ per mole of adsorptive. Finally, costs (investment cost, cost of supplying thermal energy during temperature swings, cost of electrical energy for compressors or vacuum pumps during pressure swings) will dictate the choice of regeneration method.

Figure 55. Schematic representation of temperature swing and pressure swing processes

7.1. Regeneration by Temperature Swing

Figure 56 shows an installation in which the temperature-swing process is used. To remove adsorbate, the adsorbent is heated either indirectly via an external double jacket and an internal heating surface or directly via a hot gas. The remaining residual loading depends on the final temperature of the adsorbent and, possibly, the adsorptive loading of the hot gas. The temperature-swing process can be used efficiently only if the loading of the adsorbent decreases substantially as temperature increases. This is the case, for example, for the system water – molecular sieve. If the regenerating gas at a temperature of 200 °C (or 300 °C) has a partial pressure $p(H_2O)$=1.5 kPa and if it is used to heat to 200 °C (or 300 °C) a molecular sieve bed with an equilibrium loading X=0.22 kg/kg at 25 °C, the loading decreases to X=0.04 kg/kg (or 0.015 kg/kg at 300 °C). Regeneration costs are determined primarily by the course of the adsorption isotherms and the temperature difference between adsorption and desorption. In addition, the heating of a larger fixed bed may take hours because the adsorbents have low thermal conductivity.

In direct heating, the heated regeneration gas often flows countercurrently, i.e., in the direction opposite to that of the gas treated in the preceding adsorption step. Thus, a very clean zone at the end of the fixed bed, with a very low residual loading of adsorbent for the following adsorption step, results. In some applications, the required bed length decreases, so that investment and operating costs are reduced.

Figure 56. Adsorption unit with regeneration of adsorbent by the temperature swing process

Equilibrium diagram shows adsorption isotherms of water vapor on a 0.5 nm molecular sieve.

a) Heating; b) Cooling

Closed-circle regeneration is advisable when the gas to be treated and the heated regenerating gas must not be mixed. A blower circulates the regenerating gas—often an inert gas, cleansed of adsorptive—through a heater and a cooler. The heater warms up the gas before it enters the adsorber to be regenerated, while the adsorptive that has accumulated in the regenerating gas is condensed in the cooler. If the adsorber is operated at elevated pressure and the gas is heated during compression, the heat of compression can be used for regeneration by appropriate connections. To do so, part of the hot gas is sent to the adsorber to be regenerated. The gas is then loaded with adsorptive and rejoins the suitably throttled main stream of gas. In this case, the adsorptive is also condensed and removed in a cooler.

7.2. Regeneration by Pressure Swing

Regeneration by pressure swing is carried out at the approximate temperature of the adsorption step but at lower pressure. If adsorption is carried out at elevated pressure, a *release of pressure* is often sufficient. On the other hand, *vacuum* must be applied if adsorption is carried out at ambient pressure. The pressure-swing process also requires a favorable equilibrium. As much adsorptive as possible should be removed for a given pressure drop. Figure 57 shows an installation in which the adsorbent is regenerated by the pressure swing process. The equilibrium diagram contains 25 °C isotherms for both methane and carbon dioxide. If, for example, adsorption occurs at 0.1 MPa and the regeneration pressure is reduced to 25 kPa, the loading of methane drops from 0.075 to 0.025 kg/kg, but that of carbon dioxide drops only from 0.186 to 0.169 kg/kg. Although carbon dioxide can be removed at very low regeneration pressure, energy consumption by the vacuum pump is increased. The course of the adsorption isotherms along with the pressure difference during adsorption and desorption, essentially determines the cost of regeneration. Pressure reduction is rapid, requiring only minutes or even seconds.

Figure 57. Adsorption unit with regeneration of adsorbent by the pressure-swing process

Equilibrium diagram shows adsorption isotherms for methane and carbon dioxide on 0.5 nm molecular sieve.

7.3. Regeneration by Displacement

During regeneration by displacement, the adsorbate is removed from the adsorbent by displacement from the active sites due to adsorption of a third material (the displacing agent). Examples are the removal of organic substances from active carbon by steam (see Section Removal of Organic Components from Exhaust Air) and the displacement of long-chain by short-chain alkanes from zeolitic molecular sieves (see Section Separation of Isomers). The choice of a suitable displacement agent depends both on the equilibrium of the system and on the kinetics of adsorption and desorption.

The most common displacing agent is steam, especially when water and adsorptive are immiscible. To prevent early condensation at the top of the column supersaturated steam at about 130 °C and 1 bar is preferentially used [134-136]. Characteristic is also the occurrence of a water front within the adsorber [137]. This should not be confused with the mass-transfer zone, which is not very sharp during desorption. At higher residence times the superheated steam desorbs water and leads to a drying effect behind the water front. This results in a distinct maximum water loading in the bed (Fig. 58). Steam flow in the same direction as the flow direction during adsorption is thus advantageous [137, 138].

Figure 58. Axial loading profiles of toluene and water after adsorption and desorption

The commonly applied drying in the same flow direction as in the previous adsorption step gives almost the same results as if no drying was done. It has been shown [136] that an internal local desorption/adsorption process, due to pronounced differences in the rate-determining step of mass transfer on the local particle, is the cause of this inefficiency. To achieve a long breakthrough time with an environmentally acceptable low emission level, a long part of the bed must be regenerated towards too low loading levels. If this low-loaded part is too short, the activated carbon cannot adsorb the solute in the necessary amount. That means the exit gas concentration of the column is too high for environmental purposes. If this limit has to be fulfilled, the length of the well-cleaned part of the bed must be long enough to enable a sufficient mass transfer, even when only a small driving force between the gas and the carbon phase exists. Otherwise, if the part of the column which has a sufficient low residual carbon loading is too short, early breakthrough will occur. This is why a drying countercurrent to the adsorption step is always of benefit [136].

To save energy and costs the adsorbent is not fully dried and there is also a residual loading profile of the adsorbate. The experimental investigation of sorption cycles in a small technical column [136, 138] revealed that the regeneration conditions influence the following adsorption much more than the type of adsorbent used.

7.4. Regeneration by Extraction

In regeneration by extraction, the adsorptive is picked up by an extracting agent which is brought into contact with the loaded adsorbent. In this manner, adsorbed sulfur can be extracted with carbon disulfide or a solution of caustic soda (see Section Adsorptive Desulfurization Processes). Adsorbents loaded with sulfuric acid can be regenerated by extraction with water or ammonia.

7.5. Reactivation of Adsorbents

Reactivation may be necessary when the adsorbate is not volatile or soluble enough to be desorbed by increasing the temperature, reducing the concentration, or extracting

with solvents. This is the case for adsorbates on granular *activated carbon* during water purification or during decolorization of sugar-beet juices. Adsorbed organic impurities coke during heating and permanently damage the adsorption agent. New pores for adsorption can then be created by gas activation with carbon dioxide and gas containing water vapor at ca. 900 °C (⟶ Carbon – Carbonaceous Adsorbents).

This type of regeneration always entails a loss of activated carbon because it involves a chemical reaction between activated carbon and the regenerating gas. Additional losses occur due to mechanical abrasion during transport and in the furnace. In general, a loss of ca. 10 % is necessary to regain 90 – 95 % of the original adsorption capacity. Higher capacity entails higher losses and vice versa.

Powdered coal can be reactivated as a sludge by atomization in a combustion chamber at 850 – 900 °C and at a residence time of about 1 s [139].

Thermooxidative regeneration may also be required for *molecular sieves* if polymers or carbon deposits have formed on the adsorbent. The impurities must then be burned off under controlled conditions at low oxygen concentration and about 500 °C.

Fuller's earth, which is used in the treatment of edible oil or mineral oil products, is also regenerated thermally or oxidatively. First, the adhering oil is extracted with a solvent; then the fuller's earth is heated in a stream of oxygen-containing gas to 350 – 550 °C. During this treatment, carbon and organic substances are burned off. This regeneration can be carried out in a fluidized bed of low bed height, placed in a vibrating channel, at residence times of a few minutes. Temperature treatment is followed by an acid wash and drying.

7.6. Liquid Phase Desorption

Adsorbents used in liquid-phase processes are regenerated similarly as described above for gas-phase processes. However, thermal activation will cause losses of the adsorbent of about 5 – 15 %. This is feasible with activated carbon, alumina, and pillared clays but not economical with expensive sorbents like zeolites or polymeric adsorbents.

However, highly volatile adsorbates are easily removed by a temperature swing with hot purge gas, for instance, when drying organic liquids or compressed gases and then removing water by TSA. Desorption with steam is similar in price to extractive desorption, whereas the greater flexibility of the latter leads to broader application. The efficiency of chemical regeneration is higher when small-molecule solvents which can enter the micropores are used [140, 141]. In many cases it can be performed in situ and there is then a need to distillate the extract prior reuse. Also the bed has to be backwashed or steam-stripped to remove entrained solvents [66, 142].

Other methods are to change the ionic strength or pH value. The latter is applied with dissociating species, since the undissociated form is better adsorbed. Thus, organic acids, phenols, polyphenols, and their derivatives are more easily desorbed at a high pH. High salt concentrations promote a salting-out effect, and regeneration can then be performed with pure water [143]. These salt effects are seldom used, but the general rule is that small ions act as salting-out agents, whereas large ones tend to salt-in [144]. Alternative solvents, like supercritical fluids (liquid CO_2, etc.) or micellar surfactant solutions, are not commonly applied for reasons of cost.

[Top of Page]

8. Gas Phase Processes

Adsorption processes in the gaseous or liquid phase are used either to remove certain components from a fluid phase (e.g., air, water) or to separate a mixture.

The diameter of fixed-bed adsorbers depends on the permissible superficial velocity of the fluid when pressure loss is considered. The so-called *F* factor $\dot{v}\sqrt{\rho}$ is often between 0.05 and 0.5 m s^{-1} $kg^{1/2}$ $m^{-3/2}$. The pressure drop Δp of a fluid flowing through a fixed bed of spherical particles with height *Z* and porosity Ψ is

$$\frac{\Delta P}{Z} = \xi \frac{(1-\psi)}{\psi^3} \frac{\dot{v}\rho}{2} \frac{1}{2R_a} \tag{8.1}$$

where the drag number ξ depends on the Reynolds number *Re* ψ (see Fig. 59).

Figure 59. Drag number ξ as a function of Reynolds number *Re* ψ for various packings

a) Coke and ore packings; b) Raschig rings; c) Berl saddles; d) Irregular sphere packings; e) Regular sphere packings

The length of the adsorber primarily depends on the length of the mass-transfer zone and the length of the unused bed (LUB) as well as the cycle time.

In addition to fixed beds, moving and fluidized beds are utilized for gases and liquids. Liquids can also be treated adsorptively by being brought into contact with adsorbents in mixers. After adsorption, the suspension is separated mechanically by filtration, sedimentation, or centrifugation.

Industrially important processes generally involve the separation of gas mixtures, often using the pressure swing process. These may include the removal of water from various gases (CO_2, SO_2, H_2S, NO_x) and organic or radioactive materials from air, exhaust gas, or flue gas. The adsorptive purification of natural gas, hydrogen purification, the removal of CH_4, CO_2, CO, and N_2, and the separation of isomers are also important.

8.1. Adsorptive Separation of Gas Mixtures

Mixtures in the gas or vapor phase can be separated by rectification (⟶ Distillation and Rectification), absorption (⟶ Absorption), membrane separation processes (⟶ Membranes and Membrane Separation Processes), partial condensation or desublimation, or adsorption. Adsorptive separation may be based on *steric, equilibrium,* or *kinetic effects*.

With the *steric effect*, only molecules whose critical diameter is less than the diameter of the micropores are adsorbed in the latter. A mixture is thus separated by molecular size. Both zeolitic molecular sieves with cage openings of 0.38, 0.43, 0.5, 0.8, or 0.9 nm and carbon molecular sieves with micropore widths of 0.3, 0.35, or 0.5 nm are utilized in adsorptive separation based on the steric effect. Examples are the separation of iso- and *n*-alkanes by using molecular sieve 5A (0.43 nm) and the separation of nitrogen and oxygen by using a carbon molecular sieve.

In addition, mixtures of gases can be separated by a *kinetic effect* if one component is adsorbed much faster than the other(s). This is generally due to the higher micropore diffusion coefficient of the first component. Depending on the average size and distribution of micropores, the steric or the kinetic effect may predominate. If the critical molecular diameter of an adsorptive is almost the same size as the diameter of the micropores, a *steric – kinetic effect* can occur because adsorptives with smaller molecular diameters are adsorbed much more rapidly.

Separation of mixtures by the *equilibrium effect* is based on one component being bound more strongly than the other(s). A large distance between single-component adsorption isotherms favors this effect (see Fig. 60). Highly bulging equilibrium curves are thus obtained, as shown in Figure 61. Thus, for example, methane – ethane mixtures can be separated with activated carbon [145] and nitrogen – oxygen mixtures with molecular sieve 5A based on the equilibrium effect.

In adsorptive separation processes, loaded adsorbents can be regenerated by temperature swing, pressure swing, or displacement by an additional component. Pressure swing processes are widely used for a number of gaseous mixtures whose components are adsorptively bound at only moderate strength.

Figure 60. Single-component adsorption isotherms for methane and ethane on activated carbon at 20°C [66]

Figure 61. Mixed adsorption equilibrium during adsorption of methane and ethane on activated carbon at 20°C [90]

8.2. Pressure Swing Processes

In pressure swing processes, the following steps occur successively: 1) pressure buildup, 2) adsorption at high pressure and hence production of a pure component, 3) depressurization, and 4) purging at low pressure or under vacuum (see Fig. 62). Step 4 is not always necessary.

In an installation that is run continuously with constant feed of a mixed stream, several units are placed side-by-side. The number of adsorbers is at least two. Because the four steps are of unequal duration, a larger number of adsorbers may be more cost efficient.

During depressurization, a portion of the bound adsorptive desorbs, due partly to the pressure swing effect and partly to the increased temperature of the adsorbent resulting from the heat liberated in adsorption (temperature swing effect). When the bed is at low pressure, it is purged usually with pure product component. In a sense, this corresponds to reflux during rectification (⟶ Distillation and Rectification – Continuous Rectification (Multiple Distillation)), the reflux ratio being dictated by the desired purity of the product and being at least one for a linear adsorption isotherm [146]. During adsorption, the component that is more weakly bound is generally obtained in fairly pure form. The more strongly bound component becomes the desorbate during regeneration. If its purity is not adequate, an additional adsorptive separation can follow.

Figure 62. Pressure-swing process with four beds

A) Adsorptive separation of different impurities from hydrogen; B) Pressure change in individual beds as a function of time: At t=0, adsorption occurs in bed 1 at the highest pressure of the process; bed 2 is being partially depressurized; bed 4 partially pressurized; the flash gas of bed 2 is used as stripping gas for bed 3; bed 4 is pressurized by part of the pure gas and is used as an adsorber in the next step

a) Pressurization; b) Depressurization – pressurization; c) Depressurization – purging

If several components are to be removed adsorptively, a bed with zones containing different adsorbents (mixed bed) can be used. For example, if both water and carbon dioxide are to be removed from air, water can be separated on activated aluminum oxide as soon as the gas enters; then, carbon dioxide can be removed by using a zeolitic molecular sieve. Because the curvature of the adsorption isotherms is slight in both cases, pressure swing regeneration presents no problems (see Section Regeneration by Pressure Swing).

The choice of adsorbent depends primarily on the separation effect employed. If separation is carried out on the basis of the equilibrium effect, the adsorption isotherms should be approximately linear so that the resulting rate of desorption by depressurization is not too low. Although the capacity of the adsorbent decreases with increasing temperature, the linearity of an isotherm favorable to adsorption increases. The choice of a proper pressure ratio p_{ad}/p_{des} is particularly important and depends on the position and shape of the isotherms. Table 7 lists examples of adsorptive separation by the pressure-swing process [147-153]. Several of these are very important in industry and are explained in more detail.

Table 7. Examples of pressure-swing proceses

Mixture	Adsorbent	P_{ad}/P_{des}, MPa/MPa	T, °C	Ref.
H_2 isotopes	Pd on AO	0.79/0.15	25	[147]
$H_2 – CO_2$	CMS, ZMS, AAO			
$H_2 – N_2$	CMS, ZMS, AAO			[148]

$H_2 – H_2S$	CMS, ZMS, AAO			
$N_2 – O_2$	CMS, ZMS			[148]
	CMS	0.6, 0.7, 0.8/0.1		[149]
	CMS	0.35, 0.18/0.01		[149]
$CO_2 – CO$	CMS			[148]
CO_2 – air	ZMS “Zeosorb” 13 X	10/0.013	5 – 20	[150]
$N_2 – CH_4$	ZMS 5 A	0.14/0.006	25	[151]
$N_2 – C_2H_4$	CMS 5 A	0.34/0.1	30	[152]
$O_3 – O_2$	ZMS, SiO2			[153]

*AAO = activated aluminum oxide, AO = aluminum oxide, CMS = carbon molecular sieve, ZMS = zeolitic molecular sieve.

8.3. Separation of Nitrogen from Oxygen

Nitrogen – oxygen mixtures can be separated adsorptively (see also ⟶ Nitrogen – Air Separation by Adsorption) by both the equilibrium and the steric effect, depending on the type of adsorbent used.

Separation by the Equilibrium Effect. The adsorption of oxygen on zeolitic molecular sieves is weaker than that of nitrogen (see Fig. 63) [145, 154]. Based on the equilibrium effect, the gas leaving the adsorption step is rich in oxygen. The desorbate resulting from pressure-swing regeneration consists largely of nitrogen. The purity of oxygen can be as high as 95 %, which is satisfactory for some applications. Adsorption is carried out conveniently at a pressure of 0.6 MPa and at ambient temperature. For desorption, the pressure is lowered to 0.1 MPa.

Figure 63. Equilibrium curve of nitrogen–oxygen system on molecular sieve 5 A at –130°C and 0.1 MPa

Separation by the Steric Effect. Nitrogen – oxygen mixtures can also be separated on carbon molecular sieves with micropores of 0.3 nm, based on the steric effect [145, 155]. The critical molecular diameters of oxygen and nitrogen are 0.28 and 0.3 nm, respectively. This means that nitrogen molecules can force their way into the micropores only by micropore or crack diffusion. For that reason, oxygen is adsorbed much more rapidly than nitrogen, as shown in Figure 64, where the relative loading X/X_{max} of a pellet is plotted as a function of time for oxygen and nitrogen. Within a short time, the pellet is almost loaded with oxygen while the adsorption of nitrogen is considerably

lower. The purity of nitrogen is as high as 99 %, and that of oxygen, ca. 80 – 98 %, depending on the process steps and the operating procedure. The bed loaded with oxygen is regenerated either by evacuation to 10 kPa or by purging with a gas component at atmospheric pressure [155].

Separation on carbon molecular sieves based on the equilibrium effect is much less favorable because the adsorption isotherms of oxygen and nitrogen on carbon molecular sieves are relatively close together.

Figure 64. Loading as a function of time for oxygen and nitrogen on a carbon molecular sieve at 20°C

8.4. Adsorptive Purification of Air

Drying of Air. Industry frequently requires air with a very low *dew point.* Examples are control air for pneumatic controllers, air for ventilating storage tanks of organic liquids, and process air for the chemical industry.

Air can be dried with the aid of zeolitic molecular sieves, silica gel, and activated alumina. These adsorbents are usually regenerated by the temperature swing process. The regeneration temperature depends on the dew point desired and hence on the residual loading of dried air. Some regeneration temperatures and heat consumption per kilogram of water to be removed are listed below:

Silica gel	120 – 150 °C	ca. 8000 kJ/kg
Aluminum oxide	160 – 190 °C	ca. 11000 kJ/kg
Molecular sieve	200 – 300 °C	ca. 12000 kJ/kg

With silica gel, dew points of dried air of ca. –60 °C can be attained; with aluminum oxide, ca. –70 °C; and with molecular sieves, ca. –80 °C. The relation between the saturation concentration of water vapor in air ($c^* = p_s/RT$) and the dew point is shown in Figure 65.

If the air to be dried is compressed to more than 0.5 MPa, the adsorbent can also be regenerated by pressure swing. To do so, part of the stream of dried gas is expanded and conveyed countercurrently into the previously depressurized loaded adsorber. During the adsorption step, the pressure is at least 0.5 MPa, while desorption is carried out at 0.1 MPa.

Removing Traces of Oil. If the air contains traces of oil in the form of droplets or vapor, these can be efficiently removed by activated carbon beds. Loaded beds are usually regenerated with steam.

Figure 65. Saturation concentration $c^*=p_s/RT$ of water as a function of temperature

8.5. Removal of Radioactive Nuclides from Exhaust Gas

Exhaust gases of nuclear power stations contain gaseous radioactive nuclides such as tritium, nitrogen, oxygen, argon, krypton, and xenon in concentrations far below 10^{-6} vol % [156]. Hydrogen-containing tritium is burned catalytically, and the water is purified. Short-lived nitrogen, oxygen, krypton (except ^{85}Kr), and xenon nuclides (half-lives from a few minutes to a few days) are adsorbed on activated carbon, the bed providing lag time for radioactive decay. Tests have shown that activated carbon with a micropore diameter of about 0.65 nm has the highest retention factor for krypton.

Since ^{85}Kr has a half-life of 10.7 years, the principle of lag time cannot be used. It is therefore adsorbed on activated carbon or molecular sieves at low temperature (–40 to –196 °C). The loaded adsorbent can be regenerated by heating to 20 – 100 °C, by lowering the pressure, or by purging with inactive gas.

Radioactive iodine is separated on activated carbon impregnated with potassium iodide. In so doing, isotope exchange takes place. Radioactive iodine, in the form of silver iodide and iodate, can also be bound by a chemical reaction to catalyst carriers based on ceramics that have been coated with silver nitrate.

8.6. Removal of Organic Components from Exhaust Air

Organic materials are most frequently separated from exhaust air by adsorption on activated carbon, the loaded adsorbent being regenerated by displacement desorption with steam. This is particularly advantageous if the organic substance is insoluble or sparingly soluble in water, because the mixture formed during regeneration (steam + vapor of organic component) can then be separated readily into two liquid phases after condensation.

Occasionally, molecular sieves are used as adsorbents because they can be regenerated by purging with a heated gas. In principle, this type of regeneration can also be employed with activated carbon. The adsorbent is then purged with an inert gas (e.g., nitrogen) which circulates through a condenser and a heater. The organic materials are condensed in the cooler. The heater serves to preheat the purge gas before it enters the adsorber.

Figure 66 depicts an installation for purifying exhaust air in which organic components are adsorbed on activated carbon and the loaded adsorbent is regenerated by steam. The exhaust air, which contains organic materials, flows from the bottom to the top through the bed of activated carbon (a). When the exit concentration reaches permissible values (between 20 and 150 mg/m^3, according to the 1986 clean air regulations in the Federal Republic of Germany (TA Luft) [157]), the stream of exhaust air is directed to the regenerated adsorber. Superheated steam flows countercurrently, from top to bottom, through the loaded fixed bed, displacing the organic materials. The mixture of steam and organic vapors is liquefied in the condenser (c). The regenerated adsorber is then dried by means of a hot gas and later cooled with a cold gas.

The concentration of organic materials attainable in the purified gas depends on the conditions of bed regeneration (temperature and residual loading of water), especially of the top layer. Other important factors are the water vapor content of the air and thus its relative saturation with water vapor [158]. This can be understood by considering the adsorption isotherms of water, methanol, and the aromatic compounds benzene and toluene (see Fig. 67). Although activated carbon strongly adsorbs benzene and toluene at low relative saturation φ because of its hydrophobic character, and only weakly adsorbs water, it still accumulates considerable amounts of water by capillary condensation at $\varphi > 0.5$.

Figure 66. Schematic of an installation for purifying exhaust air

a) Adsorber; b) Blower; c) Condenser; d) Pump; e) Separator; f) Stripping column; g) Evaporator

Figure 67. Adsorption isotherms on activated carbon at 20°C

a) Benzene (nonpolar); b) Toluene (nonpolar); c) Methanol (weakly polar); d) Water (highly polar)

As a result, the lower the water vapor content of the air, the greater is the adsorption capacity for organic compounds [158, 159]. Figure 68 shows the effluent loading with toluene as a function of time for air at 21 °C, initially loaded with about 1 g of toluene per cubic meter of air, at relative water saturation φ between 0.30 and 1 [158]. These studies and others on methylene chloride and methyl isobutyl ketone have shown that moisture in the gas does not impair complete purification at very low concentration. However, insufficient evaporation of organic vapors and insufficient removal of condensing water vapor from the pores of activated carbon lead to higher contents of organic components in the purified gas. The amount of steam that condenses should just suffice to heat the activated carbon so as to desorb the organic materials [158]. In this case, water loading will be less than about 0.1 kg per kilogram of activated carbon, and very little capillary condensation will occur. During the adsorption step, the molecules of organic substances can then penetrate the pores rapidly.

Tests have shown that using superheated steam and preheating the activated carbon to be regenerated both favorably affect the attainable concentration of purified gas, as well as the adsorption capacity of the bed [159]. This is illustrated in Figure 69, in which the effluent loading is shown as a function of the loading time for various temperatures of regenerating steam, with and without preheating of the bed, and for two different amounts of regenerating steam, 3 and 6 kg of steam per kilogram of organic material. Almost equal purification can be obtained when the amount of steam is lowered from 6 to 3 kg/kg if the steam is superheated to 150 °C and the bed is preheated to about 125 °C.

Figure 68. Separation of ca. 1 g/m^3 of toluene from moist gas

H. 50%, abs. humidity 10 g/m^3; d) Temperature 21°C, toluene 0.9 g/m^3, R. H. 30%, abs. humidity 6 g/m^3 (effluent loading monitored with flame ionization detector)
B. Adsorber which was investigated (adsorption on activated carbon Supersorbon Td IV)

Figure 69. Effluent concentration of toluene as a function of loading time for various states of regeneration

a) 3 kg of steam per kilogram of organic material, temperature of regenerating steam (ϑ) 100°C, without preheating; b) 3 kg/kg, ϑ=150°C, without preheating; c) 3 kg/kg, ϑ=100°C, with preheating; d) 3 kg/kg, ϑ=150°C, with preheating; e) 6 kg/kg, ϑ=150°C, without preheating; f) 6 kg/kg, ϑ=150°C, with preheating

After steaming, care must be taken to dry and cool the bed of activated carbon as much as possible, because this favors complete purification in the subsequent adsorption step. The lower the temperature of the regenerated bed, the better is the purification.

Investigations of the sorption kinetics for toluene and 1-butanol adsorptives at concentrations up to 5 g/m^3 (STP) [160] on activated carbon showed only minor temperature increases within the pellets. Adsorption can therefore be regarded as isothermal. Checks of measured loading curves according to the pore diffusion model (Eq. 6.2) showed that the diffusion coefficients determined from the measured values (i.e., 2.9×10^{-5} m^2/s for toluene and 1.5×10^{-5} m^2/s for 1-butanol) were higher than those during molecular diffusion in air. This suggests that additional transport mechanisms (e.g., mass transport in the sorbate phase) contribute substantially to total mass transport in the particle. The model takes into account the curvature of the adsorption isotherms. Besides macropore diffusion in both the fluid and the adsorbed phase, external mass transfer to the pellet and thus resistance in the outer boundary film, must be taken into account to calculate the measured adsorption curves with sufficient accuracy.

8.7. Adsorptive Desulfurization Processes

Sulfur-containing compounds in synthesis and flue gases, especially hydrogen sulfide, carbon disulfide, carbonyl sulfide, sulfur dioxide, and mercaptans can be removed adsorptively. For synthesis gases, sulfur-containing components must be removed down to the last few parts per million to protect the catalyst.

At higher concentration, hydrogen sulfide can be separated on activated carbon from gases that are completely free of oxygen. Loaded activated carbon is regenerated by temperature swing with a hot gas, the result being a gas rich in hydrogen sulfide.

If the concentration of hydrogen sulfide is low (<50 g/m^3) and the exhaust gas contains oxygen, elemental sulfur separates on activated carbon. Hydrogen sulfide and sulfur dioxide can react at 125 – 150 °C to give elemental sulfur according to the Claus reaction:

$$SO_2 + 2\,H_2S \Leftrightarrow 3\,S + 2\,H_2O$$

Elemental sulfur accumulates on the adsorbent. This sulfur can be recovered in very pure form by hot-gas desorption. The catalytic adsorbents used are aluminum oxide and impregnated, activated carbon. The total conversion of sulfur-containing compounds is between 95 and 98.6 %, depending on the adsorbent; this can be increased to 99.4 % in a two-stage unit. Gases with low concentrations of hydrogen sulfide can be purified at room temperature with activated carbon impregnated with potassium iodide. Thus, hydrogen sulfide can be removed to a residual concentration of less than 1 ppm. Carbon loaded with elemental sulfur, can be regenerated by extraction with carbon disulfide or caustic soda.

For *exhaust air from viscose staple and yarn plants* which may contain hydrogen sulfide and carbon disulfide, adsorption on two layers of activated carbon (Sulfosorbon process) is available (see Fig. 70). The lower layer of wide-pore activated carbon (b) serves for the catalytic conversion of hydrogen sulfide to elemental sulfur according to the reaction

$$2\,H_2S + O_2 \Leftrightarrow 2\,S + 2\,H_2O$$

Carbon disulfide is adsorbed in the upper layer (a) and is displaced from time to time by steam to regenerate the activated carbon. When, after a longer period of time, the lower layer of activated carbon is loaded with sulfur, the latter is removed by extraction with hydrogen sulfide (d). The sulfur – hydrogen sulfide mixture can be separated by distillation (f). The regenerated carbon is separated from the condensate by steaming. Through various purification steps, high purity sulfur and hydrogen sulfide are finally obtained. Off-gases containing small amounts of carbon disulfide, carbonyl sulfide, and the lower mercaptans can be purified by alkalized (e.g., potassium carbonate) activated carbon in the presence of steam and oxygen. First, hydrogen sulfide is formed by hydrolysis; then, it is transformed by oxygen and alkali to the sulfate, which can be leached out with water. After this, the carbon must be reimpregnated.

Figure 70. Schematic of a Sulfosorbon plant

a) Carbon disulfide adsorption; b) Hydrogen sulfide reaction; c) Carbon disulfide desorption; d) Sulfur extraction; e) Separation; f) Distillation; g) Carbon disulfide to extraction

In *flue-gas desulfurization* with activated coke, sulfur dioxide is bound to coke in the form of sulfuric acid, according to the equation [161]:

$$SO_2 + H_2O + 1/2\,O_2 \Leftrightarrow (H_2SO_4)_{ads}$$

A suitable installation is shown in Figure 71. Regenerated activated coke moves through the moving bed adsorber and is loaded with sulfuric acid. Flue gas flows through the bed in cross flow. This results in a moderate pressure drop of the gas due to the relatively short flow length, a desirable situation in view of the large volume streams in conventional power stations. Chemisorption is carried out at ca. 120 °C and at slight excess pressure. At degrees of desulfurization greater than 85 %, sulfur dioxide loading X=0.10 – 0.15 kg/kg is achieved. The activated coke loaded with sulfuric acid is regenerated at about 600 °C by the temperature-swing process, in which coke is heated either by a hot inert gas or by hot sand (750 °C). In the schematic shown in Figure 71, activated coke is heated with an inert gas. Sulfur dioxide is desorbed as the temperature increases according to

$$2H_2SO_4 + C \Leftrightarrow 2\,SO_2 + CO_2 + 2\,H_2O$$

and coke and sand are separated by screening. The regenerated coke is cooled and returned to the adsorber pneumatically. The sand, which serves as a heat carrier, is also recirculated. In addition, loaded coke can be regenerated by washing with water, which yields dilute sulfuric acid.

a) Purification of flue gas in the adsorber; b) Regeneration of activated coke

8.8. Adsorptive Purification of Methane

Methane must often be separated from methane-containing gases such as biogas, mine gas, and deposit gas. In addition, components like water, carbon dioxide, hydrogen sulfide, sulfur dioxide, carbonyl sulfide, and mercaptans may have to be removed from natural gas. Pressure-swing processes are particularly well suited for these purposes.

Purification of Biogas, Mine and Deposit Gases. Biogas, mine gas, and deposit gases are mixtures of mainly methane, carbon dioxide, and often air. After preliminary separation of hydrogen sulfide and organic components, carbon dioxide and, to some extent, air can be separated from methane adsorptively [162]. Methane, carbon dioxide, and lower hydrocarbons are adsorbed more strongly than air on carbon molecular sieves (see Fig. 72), and separation is based on the equilibrium effect. Upon desorption, a gas rich in methane is obtained.

Figure 72. Adsorption isotherms of oxygen, nitrogen, methane, and carbon dioxide on carbon molecular sieve

During *depressurization and purging*, the gas obtained is moderately rich in methane, having a heat of combustion similar to illuminating gas. Upon *evacuation*, a gas is obtained whose methane content is comparable to that of natural gas (> 90 %). The adsorption pressure for the separation process is between 0.2 and 0.8 MPa. The yield of methane is >95 %, with less than 8 % air [163].

These separation processes can also be carried out on zeolitic molecular sieves, silica gel, and activated aluminum oxide [163]. Figure 73 shows adsorption isotherms of oxygen, nitrogen, methane, and carbon dioxide on zeolites. If an adsorbent with a very low micropore width is chosen, small molecules like carbon dioxide, nitrogen, and oxygen are adsorbed much more rapidly than methane. This is based on the steric – kinetic effect. In this way, a methane-rich gas can be obtained in the adsorption step.

Figure 73. Adsorption isotherms of oxygen, nitrogen, methane and carbon dioxide on molecular sieve 5 A (Linde)

Purification of Natural Gas. Besides its major component methane, natural gas contains materials such as water, carbon dioxide, hydrogen sulfide, carbonyl sulfide, and mercaptans which are frequently removed on molecular sieves. During drying of natural gas, dew points near –100 °C are reached if the water-loaded adsorbent is regenerated thermally. Carbon dioxide is separated on zeolitic molecular sieve 4A or 5A. At high pressure, considerable coadsorption of methane occurs, as shown in Figure 74.

Figure 74. Effect of methane on the change in loading of carbon dioxide on molecular sieve 5 A (*p* is the active pressure)

The breakthrough curves in fixed-bed adsorbers become flatter with increasing pressure in the region between 2 and 8 MPa [164]. This results from decreasing diffusion coefficients, because (see Eq. 6.31) these coefficients are inversely proportional to pressure. The height of the mass-transfer zone (HTZ) and the length of unused bed (LUB) therefore increase linearly with pressure, as shown in Figure 75. Solid lines apply to the ternary mixture hydrogen sulfide – carbon dioxide – methane, while dashed lines refer to the binary mixture hydrogen sulfide – methane.

Experimentally determined breakthrough curves can be checked by calculation according to a model that considers external mass transfer and macropore diffusion only in the gaseous phase. Optimization calculations show that an operating pressure of approximately 6 MPa leads to maximum breakthrough times if only hydrogen sulfide is to be separated from methane to a purity of 5 mg of H_2S per cubic meter [164]. The presence of 1 mol % CO_2 leads to substantially shorter breakthrough times in the ternary than in the binary mixture.

Mercaptans can be separated by using zeolitic molecular sieve 10A with a cage opening of 0.74 nm.

Figure 75. HTZ and LUB of the hydrogen sulfide component as a function of total pressure at different concentrations of carbon dioxide

a) H_2S–CO_2–CH_4, average mole fraction of CO_2 at the inlet y_{0,CO_2}=1 mol%, average mole fraction of H_2S at the inlet y_{0,H_2S}=0.1 mol%, average superficial velocity $\dot{v}$ =0.113 m/s; b) H_2S–CH_4, y_{0,H_2S}=0.1 mol%, $\dot{v}$=0.154 m/s

8.9. Adsorptive Purification of Hydrogen

Hydrogen from the production of synthesis gas contains nitrogen, carbon monoxide, methane, carbonyl sulfide, hydrogen sulfide, and other materials. These components can be removed by adsorption on zeolitic and carbon molecular sieves [148, 165]. Because practically no adsorption of hydrogen occurs, it can be obtained in highly pure form with very few parts per million of impurities. Adsorption is carried out at high pressures between 2 and 5 MPa and at ambient temperature. The adsorbents are regenerated by depressurization to 0.1 MPa and subsequent purging. Several adsorbers are often arranged in parallel to increase the yield of hydrogen [166] because the regeneration processes of depressurization and purging, together with repressurization, take longer than adsorption. Some plants contain as many as twelve adsorbers with mixed beds (see Section Pressure Swing Processes). Depending on the amount of the components to be separated and their affinity for the adsorbent, individual adsorbers are filled with layers of different adsorbents.

Pressure-swing technology is highly economical when the crude gas contains more than 50 % hydrogen. If the gas contains higher hydrocarbons or polymerizable materials, these should be separated beforehand. This will increase the lifetime of the adsorbent.

8.10. Separation of Isomers

Normal (straight-chain) and isoalkanes can be separated by the steric effect [167, 168]. The critical molecular diameter of *n*-alkanes is 0.49 nm, while that of isoalkanes is 0.56 nm. Hence, only *n*-alkane molecules will be adsorbed on zeolitic molecular sieve 5A. The loaded adsorbent can be regenerated by pressure swing and purging or by displacement of the adsorbate with a displacing agent.

Figure 76 illustrates schematically a pressure-swing installation in which molecular sieve 5A is used as adsorbent. The feed mixture, which consists of approximately equal parts of normal and isoalkanes, is evaporated in a circulation reboiler (a) at 580 kPa. It then reaches an adsorber (c) operated at 510 kPa at a temperature of 300 °C. In the

adsorption step, a product highly enriched in isoalkanes can be obtained. During regeneration by pressure swing, the pressure is lowered to 7.0 kPa with the aid of a vacuum pump. Desorption is also carried out at about 300 °C. The desorbate, which is rich in *n*-alkanes, is returned to the adsorber via the isomerizing reactor (f). In this way, normal alkanes can be almost completely converted to isoalkanes in this plant. According to [167], the energy costs of adsorptive separation are less than half those of separation by rectification.

Longer straight-chain alkanes may have a low rate of desorption, so regeneration can require a large consumption of purge gas. Therefore, displacing the component to be desorbed by a suitable material may be more economical [169]. Figure 77 shows an installation for the separation of normal and isoalkanes according to this principle. The feed is supplied to the adsorber (a) on the left. Again, normal alkanes are adsorbed selectively based on the steric effect, while the isoalkane-enriched product reaches a rectification column (b) via a heat exchanger. Before the normal alkanes break through in the adsorption step, the adsorber is regenerated by displacing the C_{10} – C_{20} alkanes with an *n*-pentane – *n*-hexane mixture (shown on the right). The desorbate reaches a second rectification column (c) where the high-boiling C_{10} – C_{20} alkanes leave at the bottom, and the displacement agent consisting of *n*-pentane and *n*-hexane is distilled overhead. In the column (b) on the left, the displacement agent, which is itself displaced by the long-chain normal alkanes in the adsorption step, is separated from the isoalkanes and withdrawn from the bottom.

9. Liquid-Phase Processes

Adsorption processes in the liquid phase are used to remove impurities from drinking water, wastewater, and aqueous solutions. Beside this, there are major applications in the food and beverage as well as the chemical industry. In principle all the adsorbents (see Chap. Adsorbents) can be used, as with gas-phase processes. However, the regeneration may be different since the adsorbates are usually less volatile.

Organic impurities dissolved in water may be removed on activated carbon. Either carbon pellets (particle diameter 0.5 – 0 mm) or powdered carbon can be used in the suspension process. Powdered carbon can be separated from water by sedimentation, filtration, or centrifugation. The direction of flow in fixed beds is from top to bottom. If the resistance of the bed becomes very high because of dirt deposits, the bed can be cleaned by back purging and loosening of the layer. Loaded carbon is either reactivated or burned. Rotary kilns, moving beds, and fluidized beds are used in thermal reactivation [139]. Such reactors are operated between 700 and 800 °C. in order to destroy all the adsorbate. Carbon pellets to be reactivated are dried between 200 and 300 °C before they reach the reaction section of the regenerator.

9.1. Purification of Drinking Water

In the preparation of drinking water, chlorine, ozone, manganese, and iron can be removed in addition to dissolved organic compounds. Activated chlorine or ozone added as a bactericide reacts on activated carbon to form Cl^- or O_2 after the water has been treated. Dissolved iron(II) or manganese(II) ions are oxidized catalytically on the surface of activated carbon and separated as the insoluble oxide or hydroxide.

All these waste and odour components can be removed by activated carbon [170]. Also fulvic and huminic acids, which are the major components of naturally colored colloids, can be removed from surface waters (lakes, ponds, and reservoirs) effectively [140]. Furthermore, water condensate containing oil can be purified efficiently with activated carbon. An oil content of less than 1 mg per liter of pure condensate can be attained, whereby the carbon takes up 10 – 15 % of its own mass.

9.2. Wastewater Treatment

Wastewater from the chemical industry often contains organic substances that are difficult or impossible to degrade biologically. These include chlorinated and nitrated hydrocarbons, especially aromatic and polycyclic compounds. Such substances can be removed with activated carbon because their isotherms favor adsorption.

Figure 78 shows adsorption isotherms of phenol and 4-nitrophenol [124]. Isotherms of 4-chlorophenol, 2,4-dichlorophenol, benzoic acid, phenylacetic acid, dodecyl benzenesulfonic acid, and their binary mixtures can be found in [125].

The single-component isotherms often obey the Freundlich equation. By using the “ideal dilute solution” theory [171], the adsorption equilibrium for mixtures of substances can be predicted simply from the isotherms of the individual components in the pore liquid.

Figure 79 shows breakthrough curves of 4-nitrophenol on activated carbon for an initial concentration around 0.1 mmol/L. The diffusion coefficients necessary for calculating such curves can be determined experimentally by establishing the decrease in concentration of the solution as a function of time in the presence of activated carbon as it is being loaded [125].

Figure 78. Adsorption isotherms of phenol and 4-nitrophenol on activated carbon at 20°C

Figure 79. Breakthrough curves for 4-nitrophenol on activated carbon at an initial concentration of ca. 0.1 mmol/L at 20°C

a) *Z*=2 cm; b) *Z*=4 cm; c) *Z*=6 cm; d) *Z*=8 cm

The removal of ionic compounds with activated carbon is not as effective as arsenic removal with activated alumina [59]. Also iron-based adsorption media are reported to be very effective in that respect [37]. Fluoride removal is also accomplished with activated alumina [172] and pesticide removal is either by activated carbon or clay minerals [59, 170]. Ultrahigh-purity water in the semiconductor industry is produced with polymeric resins and activated carbon.

The recovery of gold in the mining industry [170, 173] is a special applications of activated carbon (⟶ Gold, Gold Alloys, and Gold Compounds – Recovery of Gold with Carbon). Nowadays, secondary mining residues with gold on the ppm level are economically processed by adsorbing gold onto activated carbon.

If fixed beds of activated carbon are used to purify wastewater containing several organic substances, the individual components can displace each other, which leads to rollover (see Section Modeling the Isothermal Fixed-Bed Adsorber). After such beds have been operated for some time, the concentration of certain displaced organic substances may be higher in the purified water than in the feedwater.

To describe such fixed bed adsorbers, the balances of various materials in the bed and in the pellet must be formulated, and Equations 6.1-6.4 must be solved.

As examples, Figure 80 shows breakthrough curves of the binary mixture 4-nitrophenol – phenol [125]. A marked rollover of the less strongly bound component, phenol, occurs. Such breakthrough curves can be calculated by using a model that includes transport in both the fluid and the adsorbed phases in the macropores, as well as external mass transfer.

Figure 80. Breakthrough curves for a mixture of 4-nitrophenol (- - -) and phenol (—) on activated carbon at 20°C

a) *Z*=4 cm; b) *Z*=12 cm; c) *Z*=20cm

One of the oldest applications of activated carbon in the food industry is decolorization of sugars. In the 1970s ca. 25 % of activated coal in the USA was consumed in the sugar industry [174]. Wine, sweet oils, and nutrient fats can be decolorized and deodorized with mixtures of activated carbon (up to 20 %) and pillared clays [175]. A similar application is the decolorization of acids. In the case of crude phosphoric acid, activated carbon is used to remove humic acids and related compounds. Citric and lactic acids from fermentation broths are deodorized and decolorized by using activated carbon, as are natural products such as quinine, caffeine, gelatine, and glycerin for use in the food industry. Debittering of citrus juices [176], color control of juices and beer, and final purification of pharmaceuticals, vitamins, and amino acids are further applications of activated carbon in liquid adsorption [174]. Polyphenols, which form complexes with proteins and thus give rise to undesirable dullness in beverages such as beer, wine, and clear fruit juices, can be adsorbed with polymeric adsorbents [177]. MCM-41 has been studied as protein adsorbent in the food industry [178], and sugar separation/removal can be achieved with zeolites. To remove short-chain sugars a specific interaction between the cation in the zeolite and the sugar is necessary. By using a hydrophobic zeolite, long-chain sugars, which are hydrophobic, can be removed [179].

9.3. Separation of Nonaqueous Substances

The recovery of *p*-xylene from a mixed xylene feedstock was performed in the first patented simulating moving bed arrangement of UOP [16] using zeolitic adsorbents. The first commercial Parex unit came on stream 1971, and UOP has licenced 72 units resulting in a nameplate capacity of 13.8×10^6 t/a. The same principle (see Fig. 15) is applied to separate *n*-paraffins from kerosene in the Molex process using molecular sieve adsorbents. Other Sorbex technologies are the separation of ethylbenzene or *m*-xylene from mixed C_8 aromatic isomers, of olefins from paraffins, *p*-cresol or *m*-cresol from other cresol isomers, *p*-cymene or *m*-cymene from other cymene isomers, and fructose from mixed sugars [180].

Organic materials of all kinds, especially solvents and liquefied petroleum gases that contain traces of water, can be dried by adsorption. Zeolites, silica gel, and activated aluminum oxide are used. If the organic liquid contains a polymerizable olefinic component, molecular sieve 3A is employed to prevent polymerization. The residual water content is below 1 ppm. As a rule, the adsorbents are regenerated thermally.

Components such as water, carbon dioxide, hydrogen sulfide, and mercaptans can be removed adsorptively from liquefied natural gas. The main bed uses 4A or 5A zeolites, which adsorb water, carbon dioxide, and hydrogen sulfide. Mercaptans are removed, in a bed connected to the outlet side, by using molecular sieve 10A. If efficient thermal desorption of hydrogen sulfide is desired, a temperature of 250 °C is required.

Mercury is a dangerous contaminant which is often present in natural gas, petrochemicals, and some refinery feed streams. Typical adsorbents used for mercury removal are activated carbon or coke [181]. A newer challenge is the desulfurization of transport fuels, the success of which will depend on the development of a highly selective sorbent with a high sulfur capacity, because zeolites and activated alumina used so far are not promising [182-186]
